In the more severe cases with persistent fevers, cardiopulmonary symptoms, significant anemia, and significantly elevated inflammatory markers, corticosteroids may be used, often given as pulsed IV methylprednisolone (30 mg/kg/dose, maximum 1 g/day) daily for 3 consecutive days, followed by tapering doses of oral prednisolone.[139] The newer biologics that inhibit IL-6 (tocilizumab) and IL-1 (anakinra, canakinumab, and rilonacept) have been shown in clinical trials to be very effective in treatment of sJIA.[112-115] The IL-1 signature found in active sJIA and subsequent response to IL-1 inhibition demonstrates a key feature in the pathogenesis of sJIA.[54,55,111] Increasingly, IL-1 or IL-6 inhibition is instituted earlier to avoid steroid toxicity, and in some recent studies, is used as initial therapy before corticosteroids.[140,141] Use of MTX and TNF inhibitors may be more helpful for more significant articular disease.[67,89] Cyclosporine, as well as monthly IV immunoglobulin, have shown some benefit in systemic symptoms and can be used for

steroid-sparing effects.[142] Abatacept has been used in patients with sJIA who have failed previous treatments. In the open-label portion of an RCT of abatacept therapy in polyarticular-course JIA patients, 65% of patients with initial sJIA subtype at onset had a response comparable with the other JIA subtypes evaluated in that study.[107] For very severe refractory cases, stem cell transplantation (SCT) has been performed, and some cases have shown benefit.[143]

The 2013 ACR guidelines for JIA treatment divided sJIA patients into two groups: (1) active systemic features, and (2) active arthritis, but the guidelines did not include patients with MAS, impending MAS, or life-threatening manifestations (e.g., cardiac tamponade).[67] The algorithm shown in Figure 107-4 also addresses severe systemic disease and MAS. The optimal treatment for MAS continues to be controversial. Therapy should be aggressive and usually starts with high-dose steroids and disease-modifying agents such as cyclosporine and IL-1 blockade.[57,144,145] Almost 50% of patients in one study showed response to steroids alone.[60] If the patient is not responding, then etoposide can be used based on the current treatment protocol for HLH.[146,147] In an attempt to avoid severe bone marrow suppression, antithymocyte globulin has been used.[57,148]

## UVEITIS

Chronic anterior uveitis, defined as inflammation of the anterior uveal tract, including the iris and ciliary body, is the most frequent extra-articular manifestation of JIA. Uveitis is most common in patients with oligoarticular JIA (17% to 26%), patients with RF⁻ polyarticular JIA (4% to 25%), and patients with JPsA (10%). It is rare in patients with RF⁺ polyarticular JIA and sJIA.[10,149] Overall, uveitis is observed in 30% of ANA⁺ patients with JIA.[150] Risk factors for uveitis include ANA positivity, age at JIA onset 6 years or younger, disease duration 4 years or less, female sex, oligoarticular JIA subtype, and JPsA subtype.[151] ANA positivity and age of JIA onset are larger risk factors in girls compared with boys.[152,153]

Chronic anterior uveitis is typically nongranulomatous, recurrent, and asymptomatic and, if unrecognized, can lead to serious visual deficits. Because of its insidious onset, regularly scheduled screening by an experienced ophthalmologist with slit lamp examination is required for early diagnosis and treatment with specific guidelines (Heiligenhaus guidelines) as shown in Table 107-3.[154] Newly diagnosed patients are ideally screened within 6 weeks of diagnosis[155] because approximately 30% of uveitis cases have been found at the onset of JIA,[156] and 5% to 10% have occurred prior to diagnosis.[157] Ninety percent of uveitis cases are diagnosed in the first 4 years after JIA diagnosis,[150] but uveitis has been reported even into adulthood.[150,158] In children with acute anterior uveitis, as can be seen in JSpa, the uveitis is usually highly symptomatic and therefore requires only annual screening. The clinical course of the uveitis and arthritis may not parallel one another.

The differential diagnoses include infectious causes, such as tuberculosis, toxoplasmosis, cytomegalovirus, herpes simplex virus, syphilis, human immunodeficiency virus, Lyme disease, cat scratch disease, and fungus. Uveitis can occur secondary to a systemic illness, such as in Behçet's disease, sarcoidosis, autoinflammatory syndromes, multiple sclerosis, TINU (tubulointerstitial nephritis and uveitis syndrome), and Vogt-Koyanagi-Harada syndrome. It is also important to not miss a malignancy such as lymphoma or retinoblastoma.[151]

The goal of uveitis treatment is to control the acute inflammation and complications, treat the underlying systemic disease, minimize medication side effects, prevent recurrences, and preserve vision. Inflammation should be controlled to less than 0.5+ cells per eye.[154] Initial treatment is to use high-potency topical corticosteroids, as well as mydriatics to dilate the eye in an attempt to prevent synechiae.[159] If there is impending vision loss, severe inflammation, ocular hypotony, or macular edema, ocular steroid injections or systemic steroids can be used. In approximately 40% of patients, the uveitis remains active, and if topical or systemic corticosteroids cannot be weaned,

alternative regimens need to be considered to prevent cataracts and glaucoma as well as ongoing inflammatory damage.[154,160,161] Although there are no RCTs on the use of immunosuppressive medications in children with uveitis, several observational studies suggest the effectiveness of these treatments.[154,162] MTX is usually the first choice [163-165] with an estimated response rate to MTX in 74%.[166] Alternative immunosuppressives include azathioprine[154,167] and mycophenolate mofetil (MMF).[168,169] Cyclosporine has limited value.[170] In cases of refractory inflammation after 3 to 4 months of MTX, TNF inhibitors are effective.[171] Infliximab and adalimumab appear to be equally effective, whereas etanercept is less effective.[171-180] Adalimumab is currently preferred over infliximab because of a higher probability of persistent remission.[175,181] There have been a few reports investigating golimumab at 50 mg SQ monthly dosing for uveitis.[182-185] For cases refractory to treatment with TNF inhibitors, there have been case series examining the use of abatacept,[186-188] tocilizumab,[189,190] and rituximab.[191] Uveitis specialists recommend tapering immunomodulatory therapy after 12 to 24 months of disease quiescence.[162-192] Treatment of uveitis requires close collaboration between the child's rheumatologist and ophthalmologist. In 2012, Heiligenhaus and colleagues. published treatment guidelines for uveitis in JIA based on the current evidence and consensus.[154]

The reported rate of visual loss due to JIA-related uveitis has decreased from 22% to 66% in studies before 1990 to 3% to 25% in newer studies, suggesting that increased screening and newer, more aggressive therapeutic approaches, including biologics and ophthalmologic surgery, are effective.[2] Risk factors for poor visual acuity include presence of posterior synechiae (Figure 107-5), band keratopathy, and glaucoma; oral steroid use; active uveitis, especially with 1+ or higher-grade anterior chamber cells; and prior intraocular surgery.[193,194]

**Figure 107-5** Chronic anterior uveitis demonstrating posterior synechiae and absence of significant scleral inflammation.

## IMAGING

Imaging is important in JIA to confirm the diagnosis—to exclude other diseases such as infection, malignancy, osteoid osteoma, or avascular necrosis; to monitor therapy; and to track disease activity. Determining the presence of cartilage loss and erosions is complicated by the anatomically changing joints during the normal growth process. Because children have a large amount of cartilage in their joints, a significant amount of destruction can occur before erosions are identified on plain radiographs. Local growth disturbances can also be seen in children, including bony overgrowth, particularly in the small joints of the hands and feet and in the knees, likely because of chronic hyperemia. In contrast, premature fusion of the epiphyses can lead to shortening of certain joints, most notably TMJ leading to micrognathia.[195-197] Interestingly, the articular cartilage of growing children has unique regenerative qualities, and studies have shown that children with JIA can have improvement in their radiographic joint damage.[197]

Plain radiographs in patients with JIA show soft tissue swelling as an early but nonspecific finding. The most common form of radiographic damage in JIA is joint space narrowing caused by erosion, thinning, and loss of articular cartilage.[193,195] Periarticular osteopenia caused by hyperemia of inflamed joints is frequently seen. Erosions and ankylosis can be seen as late findings in radiographs.[195] Joint protection is important in pediatric patients, and damage can be as frequent and as severe as in adult patients with RA, with a higher risk for bilateral hip damage in patients with JIA.[198] The trend toward early aggressive treatment to prevent erosive disease shifts the imaging need away from plain radiographs and toward other imaging modalities that are more sensitive in detecting early disease activity,[196] such as MRI and ultrasound.

Ultrasound is reliable, safe, and relatively inexpensive but not as well standardized in children as in adults. It is more sensitive than plain radiography in the detection of effusions, synovial thickening, and synovial cysts. In experienced hands, cartilage thinning and bone erosions can also be seen. When compared with healthy controls, all patients with JIA have been found to have decreased cartilage thickness in the knee and wrist joints even if no signs of active arthritis on examination. Patients with polyarticular JIA or sJIA appear to have thinner cartilage than patients with oligoarticular JIA.[82] Inflammatory involvement of the hip, shoulder, and elbow is more frequently accurately detected by ultrasound compared with clinical examination.[199,200] Color and power Doppler ultrasound can facilitate the evaluation of hyperemia and vascular abnormalities in affected joints and tendon involvement.[201]

MRI is the most sensitive imaging modality currently available for detecting synovial inflammation; however, its use is limited by expense and the need for anesthesia in younger children. With the use of contrast, accurate differentiation between active and inactive states can be established. Synovial enhancement and thickening can easily be seen,[202] and pannus volume measurements can be tracked.[203]

For evaluating bony erosions, MRI was found to be the most sensitive imaging modality in wrists of JIA patients, revealing more than twice as many erosions compared with plain radiography and ultrasound.[204]

## OUTCOMES

With earlier, more aggressive, targeted therapies, as well as the goal of achieving CID, the overall outcome of JIA is clearly improving. However, even with these new approaches, JIA can persist through adulthood and cause significant morbidity, functional disability, joint damage, and growth impairment. Although there is wide within-patient and between-patient variability, children with early disease onset and a greater number of restricted joints have the highest risk of developing long-term functional physical disability.[233]

In general, use of MTX and biologics are improving outcomes. Prebiologic cohorts suggest that 34% to 60% of patients continued to have active disease.[205,206] Children younger than 5 years had worse outcomes in achieving clinical remission, independent of ILAR category.[207] Recent reports during the biologic era showed overall improved probability of achieving CID in 2 years, yet one-third of patients transferring to adult services still required biologics for an average duration of 4.2 years.[208,209] Growth delay, a major issue for children with polyarticular JIA and sJIA, improves with TNF inhibitors.[210] The following paragraphs detail outcomes of the major JIA subtypes.

### Oligoarticular Juvenile Idiopathic Arthritis

In general, patients with oligoarthritis have a better overall outcome than patients with polyarthritis. Patients with persistent oligoarticular JIA generally have the best outcome, with 68% to 80% of patients achieving clinical remission.[13,206,211] Extended oligoarticular JIA patients usually follow a similar chronic disease course as $RF^-$ polyarticular JIA and have higher cumulative duration of active arthritis,[211] more erosive disease, and a higher risk of chronic disability.[13] Partial or complete remission on MTX can be induced in 60% to 70%,[86,212,213] whereas complete remission off medications was seen in 31% to 50% of children with extended oligoarticular JIA.[206,211] Relapses occur with disease flares occurring 2 years after remission in 45% to 47% of patients with persistent oligoarticular JIA and 56% to 67% with extended oligoarticular JIA.[207,211]

Ongoing disease activity and extension of joint involvement in oligoarticular JIA patients are related to a poor outcome and radiographic damage,[214] and therefore emphasis on control of disease activity is critical. Morbidity from long-term inflammation can cause growth problems, such as leg-length discrepancy with knee arthritis, muscle atrophy, bony overgrowth, joint contractions, and micrognathia.

### Rheumatoid Factor–Negative Polyarticular Juvenile Idiopathic Arthritis

$RF^-$ polyarticular JIA patients have variable outcomes,[9] but the overall prognosis appears to be improving.[22] Early response to treatment is an important predictor of long-term outcome.[215,216] Symmetric arthritis and early hand involvement predicts future disability and poorer overall well-being.[216,217] Approximately 30% to 52% of children will achieve complete remission, especially in the first 5 years.[206,211,218] However, flare of disease after 2 years of remission occurred in 52% to 69% of patients.[207,211]

### Rheumatoid Factor–Positive Polyarticular Juvenile Idiopathic Arthritis

Children with $RF^+$ polyarticular JIA have the most severe articular outcome, especially in the era prior to biologic therapies.[22,219,220] Inactive disease is difficult to achieve, with 84% of the disease course consisting of active disease, and only 5% to 17% of patients were able to reach clinical remission.[206,211] Despite treatment with nonbiologic DMARDs, a radiographic study showed that 9 years after disease presentation, $RF^+$ JIA polyarticular patients had more joint space narrowing and erosions (75%) compared with $RF^-$ polyarticular JIA (39%), sJIA (63%), and oligoarticular JIA patients (25%).[214]

### Juvenile Spondyloarthritis

The long-term outcome of JSpA is not well-studied, but as many as 40% of these children appear to progress to the adult form of AS. Predictors of sacroiliitis include HLA-B27 positivity, absence of DPB1*02, hip joint involvement within the first 6 months, and disease onset after 8 years of age.[221] When compared with AS, juvenile AS had less severe axial involvement but worse hip involvement and worse functional impairment.[222,223] Before the use of TNF inhibitors, which appear to be effective in severe JSpA and AS, the probability of remission was low. According to one study, if the arthritis had persisted for more than 5 years, the chance of remission was only 17%.[219] Recent studies have also shown that patients with JSpA have poorer patient-reported outcomes of pain intensity, physical function, and health status.[161,224-225]

### Juvenile Psoriatic Arthritis

Because of the heterogeneity in the patterns of arthritis in JPsA, the outcomes are variable and tend to track with the pattern of joint involvement. In one study, erosions were less common in JPsA compared with polyarticular JIA (23% vs. 46%, respectively).[40] Older reports note that JPsA patients had persistent disease activity and more evidence of physical limitations continuing into adulthood. However, in recent cohort studies, the outcomes appeared improved, with as many as 88% of patients achieving inactive disease on therapy and 50% achieving inactive disease off therapy.[40,226,25,35] This may be a result of more recent aggressive use of immunomodulatory therapy because as many as 74% of patients have been treated with at least one DMARD or biologic.[39]

### Systemic Juvenile Idiopathic Arthritis

sJIA is heterogeneous in severity, disease course, and outcome. Studies of the natural history of sJIA before biologic therapies demonstrate that the course can be (1) monocyclic, with remission within 2 to 4 years; (2) relapsing,

characterized by flares of systemic features with mild arthritis; or (3) continuous with persistent destructive arthritis, often more prominent after the regression of systemic features.[52,227] Patients with severe disease can have flares of extra-articular features at any time and may have active arthritis into adult life despite standard therapies.[227] Evidence now shows that IL-1 and IL-6 inhibitors have permitted significant disease control with no or much lower doses of corticosteroids.

Predictors of poor articular outcome in sJIA include systemic features 6 months after onset, thrombocytosis, and the presence of polyarthritis with hip involvement.[53,228,229] The mortality rate for sJIA is still perceived to be higher than other subtypes.[230] The severe growth delay seen before the use of IL-1 and IL-6 therapies is significantly ameliorated with biologic therapies.[231]

Amyloidosis was previously a major cause of death in sJIA but is now less common, most likely because of the use of more aggressive therapy to better control inflammation. Pulmonary hypertension and interstitial lung disease has been reported in case series.[232]

## SPECIAL CONSIDERATIONS IN CHILDREN

Physiotherapy (PT) and occupational therapy (OT) are crucial for all children with JIA, for range of motion, strengthening, joint protection, and endurance. Children with hand involvement need OT assessment and input regarding writing and school accommodations. Children who are seen later in their disease may already have flexion contractures that may require splinting and serial casting. Some children with marked leg-length discrepancies (resulting from overgrowth of the affected joint) may even require a shoe lift. Strict limitations from physical education at school and sports are generally not encouraged because physical activity plays an important role in rehabilitation and therapy; however, impact sports should be limited in the presence of joint effusions or when there is a concern for joint instability (i.e., C1/C2 atlantoaxial subluxation). A modified physical education program and sports activities to patients' own tolerance are recommended instead. Education is considered the child's main job, and trying to keep the child in school is of utmost importance for social and emotional growth. Children may be inconsistent in their report of pain; therefore, the physical examination becomes important to understand the true extent of disease. Growth can also be affected in children with chronic inflammation; therefore, one must be vigilant to watch for children falling off their growth curve as a sign of uncontrolled disease activity. Adolescents begin to think independently yet rely heavily on peer influences. This is a crucial time that can be extremely dangerous with impulsive decisions such as stopping medication or refusing medical care.

## CONCLUSION

The modern treatment of JIA has significantly decreased the long-term burden of disease but requires early recognition, diagnosis, and aggressive treatment to extinguish disease activity. Pediatric rheumatologists have in their favor the remarkable capacity for childhood growth and development to allow repair and restoration of function. The advent of new biologic therapies and rapid translation of basic research into therapeutic strategies as well as collaborative multicenter research networks should continue to improve the outlook for children with arthritis.

CHAPTER 108

# Pediatric Systemic Lupus Erythematosus, Juvenile Dermatomyositis, Scleroderma, and Vasculitis

Stacy P. Ardoin • Angela B. Robinson • Kathryn S. Torok • Heather Van Meter • Ann M. Reed

## PEDIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

**KEY POINTS**

- Compared with adult-onset systemic lupus erythematosus (SLE), pediatric-onset SLE is more severe, with more organ involvement and higher mortality.
- Renal and central nervous system involvement cause significant morbidity and mortality and warrant aggressive therapy.
- As survival has improved, it has become important to identify and prevent long-term complications of SLE and its therapy, including osteoporosis, infections, cardiovascular disease, and malignancy.
- Neonatal lupus is a passive autoimmune condition distinct from SLE. Infants born to mothers with circulating anti-Ro/SS-A and anti-La/SS-B antibodies are at risk for characteristic rash, hepatitis, cytopenias, cardiac conduction disease, and cardiomyopathy.
- Drug-induced lupus can occur in children and adolescents and is treated by withdrawal of offending medication and immunosuppression if needed.

### Definition and Classification

Pediatric systemic lupus erythematosus (SLE) is a chronic, incurable, multisystem autoimmune disorder with potential to involve any organ in the body, most commonly affecting the skin, joints, kidneys, lungs, cardiovascular system, hematopoietic cells, muscles, and central and peripheral nervous systems. The clinical presentation of SLE in both adults and children is heterogeneous, and disease manifestations can range from mild to life-threatening. The disease is characterized by periods of disease quiescence and flare. Approximately 20% of SLE patients are diagnosed before age 18 years and, compared with adults, onset of SLE in childhood is associated with higher mortality and more widespread and severe organ involvement.[1]

Pediatric SLE is usually defined as age of onset younger than 18 years.[2] No diagnostic criteria specific for pediatric SLE exist. Existing SLE classification criteria were developed for use in adults participating in clinical trials and are often used, albeit with limitations, in clinical practice. The American College of Rheumatology (ACR) Classification Criteria for SLE (Table 108-1)[2,3] and the more recently developed Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria (see Table 108-1) have been validated in pediatric SLE populations.[4-6] The ACR nomenclature for neuropsychiatric SLE (NPSLE; see Chapter 80), primarily derived from adult data, is used in pediatric SLE, also with acknowledged limitations.

### Epidemiology

Pediatric SLE occurs worldwide, and SLE prevalence is lower in children (2 to 26/100,000) compared with adults (20 to 150/100,000).[7,8] Reported incidence ranges from 0.4 to 0.9/100,000 per year.[9] As in adults, pediatric SLE is more common in Hispanics and non-Caucasian populations.[7,8] SLE is more likely to develop in females than males, and the ratio of female to male involvement varies across age groups. The female to male ratio is highest between puberty and menopause (ranging from 5 to 10:1), whereas before puberty and after menopause, the ratio is lower, estimated at 3 to 4:1.[10] Diagnosis of SLE at age younger than 5 years is unusual, whereas diagnosis in adolescence (between 12 and 16 years of age) is most common.[10]

### Genetics and Pathogenesis

Adult and pediatric-onset SLE share complex pathophysiology (see Chapter 79) with genetic, epigenetic, sex, and environmental factors interacting to produce widespread immune system dysregulation. Immune system abnormalities in adult and pediatric SLE include dysregulated apoptosis and clearance of nuclear debris, decreased clearance of immune complexes, abnormal function of Toll-like receptors, aberrations of interferon (IFN)-α and nuclear factor-κB (NF-κB) pathways, abnormal neutrophils and neutrophil function, disrupted B and T cell function, and production of autoantibodies.[7] SLE in both adults and children is considered a multigenic disorder. However, rare single-gene disorders can cause SLE or lupus-like disorders and usually are seen in childhood. Of these single-gene disorders, C1q deficiency is the rarest but most strongly associated with SLE. Deficiencies of C1s, C2, and C4 also increase the risk.[11] Males with Klinfelter's syndrome (XXY) have a substantially increased risk for SLE.[12] Multiple candidate genes implicated in adult and pediatric SLE are depicted in Table 108-2[13] (see Chapter 79). Earlier age of onset may suggest enhanced genetic susceptibility, and *STAT4* and *ETS1* gene mutations are associated with early age at SLE onset.[13] In addition to specific gene variants, the copy number, or "dose," of certain genes also likely influences disease susceptibility and severity.[14]

**TABLE 108-1** Classification Criteria for Systemic Lupus Erythematosus

| American College of Rheumatology (ACR) 1997 Revised Classification Criteria |
|---|
| Malar rash |
| Discoid rash |
| Photosensitivity |
| Arthritis (nonerosive, affecting ≥2 joints) |
| Serositis (pleuritis, pericarditis, or peritonitis) |
| Seizure or psychosis |
| Hematologic manifestations (hemolytic anemia, leukopenia [<4000 leukocytes/mm$^3$], lymphopenia [<1500 lymphocytes/mm$^3$], thrombocytopenia [<100,000 platelets /mm$^3$] |
| Immunologic abnormalities (positive anti–double-stranded DNA or anti-Smith antibody) |
| False-positive rapid plasma regain (RPR), positive lupus anticoagulant test result in elevated anti-cardiolipin immunoglobulin (Ig)G or IgM anti-cardiolipin antibody |
| Anti-nuclear antibody |

*For ACR criteria, the presence of 4 or more of 11 criteria is needed.

| Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria |
|---|
| **Clinical Criteria** |
| Acute cutaneous lupus |
| Chronic cutaneous lupus |
| Oral or nasal ulcers |
| Nonscarring alopecia |
| Synovitis (≥2 joints) |
| Serositis |
| Glomerulonephritis |
| Neurologic disorder (seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, acute confusional state) |
| Hemolytic anemia |
| Leukopenia (<4000 leukocytes/mm$^3$) or lymphopenia (<1000 lymphocytes/mm$^3$) |
| Thrombocytopenia (<100,000 platelets/mm$^3$) |
| **Immunologic Criteria** |
| Anti-nuclear antibody (ANA) |
| Anti–double-stranded DNA antibody |
| Anti-Smith antibody |
| Anti-phospholipid antibody (false-positive RPR, medium or high-titer IgA, IgG, or IgM anti-cardiolipin antibody, IgG, IgA, or IgM anti–β2 glycoprotein I antibody |
| Low complement (C3, C4, CH50) |
| Positive direct Coombs' test in the absence of hemolytic anemia |

†For SLICC criteria, the presence of 4 or more criteria (at least 1 clinical and 1 laboratory criterion) is needed or a biopsy demonstrating lupus nephritis with a positive ANA or anti–double-stranded DNA is needed.

Genetic inheritance alone is not sufficient to cause SLE, as suggested by the fact that only a minority (approximately 24%) of monozygotic twins are concordant for SLE.[10] Thus other factors, including epigenetics and hormonal and environmental exposures, are important in SLE susceptibility. In both adult and pediatric SLE, epigenetic changes, including histone modifications, methylation of DNA, and microRNA pattern modulate gene transcription and expression.[15]

**TABLE 108-2** Candidate Systemic Lupus Erythematosus Genes by Immune System Pathway

| Immune System Pathway | Candidate Genes |
|---|---|
| Apoptosis, DNA breakdown, debris clearance | *FCGR2B, ACP5, TREX1, DNASE1, DNASE1L3, ATG5* |
| Type 1 interferon and Toll-like receptor signaling | *TLR7, IRF5, IRF7/PHRF1, IRF8, IRAK1, IFIH1, TYK2, PRDM1, STAT4, TREX1, ACP5* |
| Nuclear factor-κB signaling | *IRAK1, TNFA1P3, TNIP1, UBE2L3, SLC15A4, PRKCB* |
| Immune complex processing | *C1Q, C1R/C1S, C2, C4A/B, FCGR2A/B, FCGR3A/B* |
| B cell function | *FCGR2B, BLK, LYN, BANK1, PRDM1, ETS1, IKZF1, AFF1, RASGRP3, IL10, IL21, NCF2, PRKCB, HLA-DR2, HLA-DR3, MSH5, IRF8* |
| T cell function | *PTPN22, TNFS4, CD44, ETS1, IL10, IL21, TYK2, STAT4, PRDM1, AFF1, IZKF1, HLA-DR2, HLA-DR3* |
| Neutrophil/monocyte function | *ITGAM, ICAMS, FCGR2B, FCGR3A/B, IL20, IRF8* |

Modified from Rullo OJ, Tsao BP: Recent insights into the genetic basis of systemic lupus erythematosus. *Ann Rheum Dis* 72S:56–61, 2013.

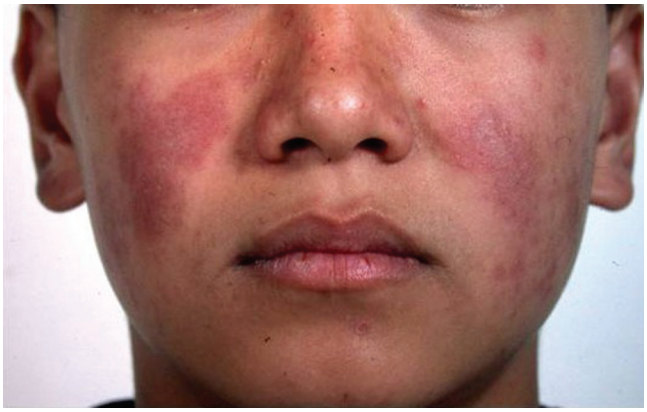

**Figure 108-1** Malar rash of a 14-year-old patient with pediatric systemic lupus erythematosus. The disease's typical "butterfly" or malar rash is an erythematous rash in the malar distribution, which includes the cheeks and crosses the nasal bridge but spares the nasolabial folds.

## Clinical Features

Pediatric-onset SLE can manifest with a vast array of clinical symptoms and findings. Renal disease can be insidious, sometimes appearing with few or no symptoms. Several common clinical manifestations of pediatric SLE are summarized in Table 108-3, and some common mucocutaneous findings are shown in Figures 108-1 and 108-2. Despite the similarities in SLE pathophysiology and genetics across the age spectrum, the clinical presentations of pediatric and adult SLE differ substantially. Children and adolescents with SLE tend to be seen with more widespread and aggressive organ involvement. Specifically,

**TABLE 108-3** Clinical Manifestations of Pediatric Systemic Lupus Erythematosus

| | |
|---|---|
| General | Fevers, fatigue, weight loss, lymphadenopathy, poor growth |
| Mucocutaneous | Alopecia<br>Acute cutaneous lupus erythematosus (malar or diffuse rash)<br>Subacute cutaneous lupus<br>Chronic cutaneous lupus erythematosus (discoid lupus, hyperkeratotic lupus, lupus tumidus, lupus profundus, chilblain lupus)<br>Cutaneous vasculitis<br>Livedo reticularis<br>Palmar erythema<br>Petechiae<br>Nasal and oral ulcers (often painless) |
| Musculoskeletal | Arthralgias, arthritis, tendonitis, myositis, loss of or reduced peak bone mass, avascular necrosis |
| Cardiovascular | Raynaud's phenomenon, cutaneous and systemic vasculitis, myocarditis, pericarditis, nonbacterial valvular vegetations (Libman-Sacks endocarditis), thrombi, and emboli |
| Pulmonary | Pleuritis, pleural effusion, interstitial lung disease, alveolar hemorrhage, shrinking lung syndrome, pulmonary embolism, pulmonary hypertension |
| Gastrointestinal | Hepatosplenomegaly, enteritis, protein-losing enteropathy, hepatitis |
| Renal | Glomerulonephritis, renal vein thrombosis, renal microthrombi, edema, hypertension |
| Neuropsychiatric | Seizures, psychosis, mood disorders, cerebritis, stroke, transverse myelitis, cognitive impairment, headaches, pseudotumor, peripheral or cranial neuropathy, chorea, optic neuritis |
| Ophthalmic | Retinitis, optic neuritis, scleritis, episcleritis |
| Hematologic | Immune-mediated hemolytic anemia, thrombocytopenia, leukopenia, hypercoaguability, thrombocytopenic thrombotic microangiopathy, anemia of chronic inflammation |
| Other | Delayed puberty, menstrual cycle disturbances, dyslipidemia |

**Figure 108-2** Oral ulcers in a 16-year-old girl with active pediatric systemic lupus erythematosus. Characteristic oral ulcers and hyperemia in children with lupus can be found on the hard palate. These ulcers are typically painless.

renal, neurologic, and hematologic involvement are more common at presentation in pediatric versus adult SLE.[16-18] Lupus nephritis is present in as many as 80% of children with SLE, but the distribution of histologic classes of lupus nephritis is similar to adults.[10] NPSLE is challenging to define, especially in developing children and adolescents. The reported prevalence of NPSLE in children and adolescents ranges from 22% to 95% and is at least as high as adult SLE rates.[19] The most common presenting findings in pediatric SLE include fever, malar rash, arthritis, glomerulonephritis, neuropsychiatric disease, and hematologic abnormalities.[10] Compared with adults, children, and adolescents with SLE typically are seen with overall higher SLE disease activity scores and are treated more frequently with moderate- to high-dose corticosteroids (CSs) and cyclophosphamide.[10,20,21]

## Diagnosis and Diagnostic Tests

Because of the heterogeneous and systemic nature of pediatric-onset SLE, the differential diagnosis is broad and often includes multiple infections (including Epstein-Barr virus, cytomegalovirus, histoplasmosis, coccidiomycosis, and tuberculosis), systemic-onset juvenile idiopathic arthritis, vasculitides, macrophage activation syndrome, malignancies (especially leukemia and lymphoma), other systemic causes of glomerulonephritis, neurologic and cardiopulmonary disease, and drug-induced lupus.

The diagnosis of pediatric SLE is clinical and is made on the basis of detailed history, meticulous physical examination, laboratory studies, and tissue biopsy when required.[22] The diagnostic approach is similar to that used in adult SLE (see Chapter 80) and usually includes assessment of complete blood count, hepatic and renal function, direct Coombs' assay testing, assessment for hemolysis and low complement levels, and measurement of anti-nuclear antibodies (ANA), anti–double-stranded DNA (dsDNA), antibodies to the extractable nuclear antigens (Ro/SSA, La/SSB, Smith, and ribonucleoprotein [RNP]), and antiphospholipid antibodies. In pediatric SLE, certain autoantibodies are detected more frequently than in adults, including anti–dsDNA, anti-cardiolipin immunoglobulin (Ig)G or IgM, anti-histone, and anti-ribosomal P antibodies.[10] As in adults, ANA-negative lupus is exceedingly rare in children and adolescents.

In the presence of abnormal urinalysis (proteinuria or cellular casts) or reduced renal function, prompt kidney biopsy is recommended. Skin biopsies often show abnormal immunofluorescence in cutaneous SLE manifestations. Diagnosis of NPSLE is challenging in children and adolescents, given normal developmental changes and increased risk of mood disorders in teens. As in adults (see Chapter 80), neuroimaging may include standard and functional MRI and positron-emission tomography (PET) imaging with technetium. Analysis of cerebrospinal fluid (CSF) may reveal nonspecific signs of intrathecal inflammation, including elevated protein levels and white blood cell counts. No serum or CSF serologic tests are diagnostic of NPSLE. Developmentally appropriate neurocognitive batteries, including pediatric automated neuropsychological assessment (peds ANAM) are used to detect and follow neuropsychological abnormalities.[19,23,24]

## Treatment

As in adult SLE, treatment of pediatric SLE is tailored to the severity of specific manifestations (see Chapter 81). Photoprotection, including regular use of sunscreen and avoidance of sun exposure, is advised for all. Hydroxychloroquine (5 to 7 mg/kg/day) is recommended for all who tolerate it because of known effects on flare reduction, lipid lowering, and potential protective effects on mortality.[25] Glucocorticoids are the mainstay for initial treatment of significant organ involvement; however, the substantial toxicity associated with long-term therapy mandates careful use. In children and adolescents, the steroid side effects of growth failure, acne, striae, and mood fluctuations can be particularly problematic. NSAIDs are used in pediatric SLE, primarily in treatment of musculoskeletal symptoms. It is not clear whether the cardiovascular toxicity associated with NSAID use in adults extends to the pediatric population. When steroid-sparing therapy is indicated, options include methotrexate (MTX), leflunomide, azathioprine, mycophenolate mofetil (MMF), cyclosporine, belimumab, and cyclophosphamide. Rituximab is sometimes used in severe or refractory pediatric SLE, despite the negative randomized clinical trials in adults. Plasma exchange and intravenous immunoglobulin are sometimes used for severe pediatric SLE. Thus far, there are no drugs specifically U.S. Food and Drug Administration approved for pediatric SLE, and treatment decisions are often inferred from adult trials. Because of its potential toxicity, cyclophosphamide is reserved for severe or refractory pediatric SLE disease. Fortunately, the risk of gonadal failure with cyclophosphamide is lower in children and adolescents compared with adults; however, many pediatric rheumatologists offer gonadotropin-releasing hormone agonists, such as leuprolide, to females to limit this risk.[26,22]

Randomized, controlled trials in pediatric SLE are rare; thus treatment approaches are often inferred from adult studies. The Childhood Arthritis and Rheumatology Research Alliance (CARRA), a network of from pediatric rheumatologists across North America, developed consensus treatment plans for newly diagnosed proliferative lupus nephritis. As outlined in Figure 108-3, these consensus treatment plans utilize oral and/or intravenous glucocorticoids, MMF, or cyclophosphamide.[27] Consensus treatment recommendations for maintenance therapy of proliferative lupus nephritis, treatment of membranous lupus nephritis, and treatment of severe central nervous system (CNS) disease and other SLE manifestations have not been published. Renal replacement therapy—dialysis or renal transplantation—is necessary in the setting of renal failure. Unfortunately, children with SLE-related end-stage renal disease (ESRD) on hemodialysis are twice as likely to die as children with ESRD from

other causes.[28] When pediatric SLE is complicated by antiphospholipid antibody syndrome, lifelong anti-coagulation is advised.

Glucocorticoid-induced osteoporosis and failure to achieve peak bone mass are worrisome complications of pediatric SLE. Ensuring adequate vitamin D and calcium intake, counseling regarding weight-bearing exercise, and avoiding risk factors, including smoking, are universally recommended. However, because of the unknown potential impact on skeletal development and future fetal development, bisphosphonates are not routinely prescribed for children and adolescents with SLE treated with steroids.[9]

Because atherosclerosis begins in childhood and is a major long-term source of morbidity and mortality in SLE, anticipatory counseling concerning cardiovascular risk reduction and screening for modifiable cardiovascular risk factors need to start at a young age. Control of blood pressure and lipids with dietary and pharmacologic interventions is indicated. The Atherosclerosis Prevention in Pediatric Lupus Erythematosus (APPLE) trial results did not suggest that statins should be routinely offered to all children and adolescents with SLE, but post hoc analyses suggested that higher-risk subgroups may benefit.[29,30]

Because of the use of teratogenic medications and the risk of SLE flare or clotting during pregnancy, teens require counseling regarding pregnancy risks and contraceptive options. Given estrogen's potential to incite flare or clotting, contraceptive medications containing significant doses of estrogen are often avoided. The results of the Safety of Exogenous Estrogens in Lupus Erythematosus National Assessment (SELENA) trial, which included adult women with low disease activity and excluded those with lupus anti-coagulant or moderate to high-titer anti-cardiolipin antibodies, suggested that oral contraceptives with low-dose estrogen increase the risk of clotting or flare in this limited population.[31]

Because infections are an important source of morbidity and mortality in pediatric SLE, immunization is critically important for prevention. The American Academy of Pediatrics recommends withholding live, attenuated vaccines from children on high-dose, chronic prednisone (defined as prednisone dose equivalent to >2/mg/kg/day or >20 mg/day if child's weight is >10 kg). Otherwise, routine vaccinations are recommended for all children and adolescents with SLE. Although data to support use in lupus are lacking, many pediatric rheumatologists used prophylactic trimethoprim/sulfamethoxazole, dapsone, or pentamidine to prevent *Pneumocystis jiroveci* pneumonia in patients on substantial immunosuppression.[22]

## Outcome

Fortunately, advances in understanding of SLE pathogenesis, diagnosis, treatment, and supportive care have improved, leading to longer survival. The 5- and 10-year survival rates, which were less than 40% in the 1960s, have increased to 80% to 90% in the 1990s. Although there is no cure for SLE, most children and adolescents with SLE are now expected to survive into adulthood. However, mortality rates are higher in pediatric versus adult-onset SLE. Across the age spectrum, early in the course of SLE, death most often occurs because of infection or severe SLE organ involvement (particularly renal and CNS disease). In the longer term, causes of mortality shift to infection, atherosclerosis, or malignancy.[9,10,22]

Because of longer exposure to disease and treatment, pediatric-onset SLE is associated with more cumulative damage as measured by the Systemic Lupus International Collaborating Clinics/American College of Rheumatology (SLICC/ACR) damage index score. In particular, development of cataracts, avascular necrosis, and renal damage are more likely to accrue in pediatric-onset SLE.[16,18] The risk of lupus-related damage is inversely related to age at onset, with prepubertal-onset SLE patients having higher risk of damage than peri-pubertal or post-pubertal.[32] Premature atherosclerosis is clearly linked to SLE, and increased carotid intimal medial thickness is evident even in children and adolescents with SLE.[30] Growth failure and delayed puberty are SLE-related morbidities unique to childhood and adolescence. Adolescents are at particularly high risk for mood disorders and poor adherence to medications, and this can influence outcomes. The transition from child-centered to adult-centered care is a vulnerable period during which adolescents and young adults with SLE are at risk for gaps in care and higher morbidity; thus efforts to improve this transition are needed. In general, poor prognostic factors for pediatric SLE include male gender, earlier age at diagnosis, Hispanic ethnicity or non-Caucasian race, lower socioeconomic status, and presence of renal or CNS disease.[9,10,22]

## DRUG-INDUCED LUPUS

Drug-induced lupus is the presence of SLE manifestations occurring after exposure to specific medications, listed in Table 108-4. Specific classification criteria for drug-induced lupus have not been published, and no published data address differences between adult and pediatric drug-induced lupus. Thus drug-induced lupus is presumed not to differ across the age spectrum. As in adults (see Chapter 80), drug-induced lupus affects males and females equally and is unlikely to cause significant renal or CNS disease. Hepatic involvement in drug-induced lupus is common. Laboratory abnormalities can include circulating antihistone antibodies, although these antibodies can also be present in SLE unassociated with drug exposure. Anti–dsDNA antibodies are less likely to occur in drug-induced

**TABLE 108-4** Drugs Implicated in Drug-Induced Lupus*

| Definite | Probable/Possible | |
|---|---|---|
| Hydralazine | Phenytoin | Hydrochlorothiazide |
| Procainamide | Ethosuximide | Sulfasalazine |

| TNF inhibitors | Captopril | Statins |

*This list is not exhaustive.

lupus than in SLE. Epigenetic abnormalities are important in drug-induced lupus, and, for example, hydralazine and procainamide can cause DNA hypomethylation. Treatment of drug-induced lupus involves withdrawal of offending medication and immunosuppressive therapy if indicated. Resolution of clinical findings may take months to years.[33]

## NEONATAL LUPUS

### Definition and Classification

Neonatal lupus (NLE) is a separate entity from SLE and is one of the few rheumatic disorders presenting in neonatal period or early infancy. NLE is a passive autoimmune condition caused by transfer of circulating maternal autoantibodies to the fetal circulation. No diagnostic criteria are available for NLE.

### Genetics and Pathogenesis

The maternal autoantibodies associated with the vast majority of NLE cases are anti-Ro/SS-A (or anti-SSA) and anti-LA/SS-B (or anti-SSB); however, anti-UA RNP antibodies have been described in NLE. Because NLE develops in only 1% to 2% of children born to mothers with these circulating antibodies, these antibodies are not sufficient to cause NLE. Although the exact pathogenesis of NLE remains unknown, a popular hypothesis based upon in vivo studies postulates that Ro and La antigens are exposed on the surface of cardiac myositis during fetal cardiac development and become a target for maternal autoantibodies. The ensuing inflammatory cascade causes damages to the conduction system and, in some cases, leads to cardiomyopathy.[34,35]

Inflammatory changes related to NLE resolve when maternal autoantibodies are cleared from the infant's circulation, typically within 6 months. Noncardiac NLE manifestations are reversible and usually do not require any treatment. Topical CSs are sometimes used to treat the rash. Because congenital heart block and cardiomyopathy can cause death and morbidity, there has been interest in finding therapies that can prevent or retard the development of cardiac involvement. Clinical trials are challenging to perform in rare diseases affecting fetuses in which placebo treatment is unpalatable or unethical. A multicenter, open-label study of 30 pregnancies and 31 fetuses showed that dexamethasone did not reverse congenital heart block. In another multicenter, prospective, open-label study, use of dexamethasone monitored 56 pregnancies in which first-degree heart block developed in 6 of 70 fetuses, 6 were treated with dexamethasone, and aterioventricular (AV) conduction system abnormalities resolved in all treated fetuses.[36,37] Two multicenter prospective studies showed that preventive treatment with intravenous Ig in mothers with circulating anti-Ro/SS-A or La/SS-B antibodies and prior pregnancy complicated by NLE/congenital heart block did not prevent congenital heart block.[38,39]

### Clinical Features

The clinical manifestations of NLE include a nonscarring malar or annular rash commonly affecting the face, scalp, and trunk (Figure 108-4). The rash usually appears in the first 6 weeks of light and can be triggered by exposure to ultraviolet (UV) light. Histologically, the cutaneous findings are similar to those in subacute cutaneous lupus. Other findings can include immune-mediated cytopenias and hepatitis (transaminitis, hepatomegaly). The most serious complication of NLE is cardiac involvement. Cardiac conduction abnormalities can present in utero (starting at 16 weeks of gestation when maternal Igs can cross the placenta) or shortly after birth and include conduction system abnormalities ranging from prolongation of the PR interval to complete heart block. In addition, endocardial fibroelastosis and progressive cardiomyopathy can develop.[34]

**Figure 108-4** A nonscarring malar or annular rash commonly affecting the face, scalp, and trunk in neonatal lupus.

### Treatment

Recent retrospective studies suggest that maternal use of hydroxychloroquine during pregnancy may reduce the risk of NLE/congenital heart block in offspring.[40,41] Given the risk for NLE, it is recommended that pregnant women with circulating anti-Ro/SSA or anti-La/SSB antibodies undergo monitoring of fetal P-R interval and cardiac function during pregnancy beginning at 16 weeks. Cardiac pacing is used in some children with complete heart block. Overall mortality in congenital complete heart block is approximately 17% to 19%. Recurrence of NLE congenital heart block in future offspring is estimated at 17%. Children and adults with congenital heart block are at risk for exercise limitations and heart failure. Given their family histories, children with NLE may be at risk for autoimmune disease.[34]

## Conclusion

Although the pathophysiology of pediatric SLE is likely similar to adult SLE, clinical presentations, prognosis, and some aspects of management differ. Children and adolescents with SLE have higher disease activity at presentation, are at substantial risk for organ damage, including renal and CNS complications, and have overall higher mortality compared with adult counterparts. Especially because children and adolescents face a lifetime burden of disease and effects of therapy, early intervention is indicated to reduce risk of long-term complications, including cardiovascular disease and bone loss. Randomized controlled clinical trials for pediatric SLE are lacking, and therefore therapeutic approaches are inferred from adult studies. However, children and adolescents require special attention to uniquely pediatric concerns, including impact of therapies on growth and body image, compliance concerns, and psychosocial and transition needs.

# JUVENILE DERMATOMYOSITIS

**KEY POINTS**

- **Juvenile dermatomyositis (DM) is an inflammatory, immune-mediated vasculopathy affecting predominantly skin and muscle.**
- **Children with DM have more vasculopathy and a greater likelihood of calcinosis or ulceration but have a better long-term prognosis with improved survival.**
- **Adults with DM are more likely to have myositis-specific antibodies, experience interstitial lung disease, and have a marked association with malignancy.**
- **Both have similar features on muscle biopsy and IFN gene signature, although subtle differences may exist in pathogenesis and pathology.**
- **Initiatives are underway to improve our classification, markers of disease activity, and ability to predict outcome of juvenile DM.**

## Definition and Classification

Bohan and Peter criteria for dermatomyositis include[42] typical skin rash of dermatomyositis, including a heliotrope rash, Gottron sign, and Gottron papules plus three of the following (two of the following would be classified as probable juvenile DM and one as possible juvenile DM):

- Symmetric proximal muscle weakness determined by physical examination.
- Elevation of serum skeletal muscle enzymes (particularly creatine kinase and aldolase), serum glutamate oxaloacetate, pyruvate transaminases, and lactate dehydrogenase.
- The electromyographic triad of short, small, polyphasic motor unit potentials; fibrillations, positive sharp waves, and insertional irritability; and bizarre, high-frequency repetitive discharges.
- Muscle-biopsy specimen abnormalities of degeneration, regeneration, necrosis, phagocytosis, and interstitial mononuclear infiltrate.

Bohan and Peter criteria date back to 1975, before the routine use of MRI, and so MRI findings are not part of the original criteria. MRI using T2-weighted images and fat suppression may localize active sites of disease for biopsy and may improve diagnostic yield. Muscle biopsy often demonstrates evidence of disease activity and chronicity that is not suspected from the levels of the serum enzymes alone; findings may be useful in grading the extent of disease and predicting disease severity or refractory disease.[43] Currently, an international multidisciplinary collaboration, the International Myositis Classification Criteria Project (IMCCP), has been working to update classification criteria for multiple myositis subtypes, including juvenile DM. The new criteria involve probability modeling for classification but have not been published yet.[44]

## Epidemiology

Juvenile DM is an autoimmune vasculopathy characterized clinically by proximal muscle weakness, muscle inflammation, characteristic rash, and frequently, the presence of autoantibodies. Juvenile DM is by far the most common form of idiopathic inflammatory myopathy in children and adolescents; therefore other types of childhood myositis are not addressed in this chapter. Although there is some overlap, DM and juvenile DM are separate diseases with variable features. Before corticosteroid treatment, mortality for juvenile DM approached 33%. Currently, juvenile DM has a 5-year survival of greater than 95%, whereas DM 5-year survival is 75% to 90%.[45-47] Incidence is 3.2 cases/million children/year in juvenile DM.[48-50] Females are affected more commonly than males in a ratio of approximately 2 : 1.[51,52] The average age of onset is 7 years of age in juvenile DM and the fourth to sixth decades in DM.[53-56]

## Genetics

The major immunogenetic risk factor for DM and juvenile DM in Caucasians is the human leukocyte antigen (HLA) 8.1 ancestral haplotype (HLA-B*08/DRB1*03/DQA1*05/DQB1*02).[57,58,59] The *HLA-DQA1*0501* allele is not only increased in Caucasians, but also in other populations and clinical disease subsets in children.[60] Protective alleles have been described in large genetic association studies in both adult and juvenile DM. Gene variation has been seen within an IFN regulatory factor 5 (IRF5) gene sequence, which may be associated with higher IFN-regulated gene expression in patients with juvenile DM.[61] Polymorphisms in TNF gene (*TNF-308A* allele) have been associated with greater disease severity in patients with juvenile DM.[62] The *TNF-308A* allele may be increased in both adult and juvenile DM; however, disease significance is lost in DM when adjusting for HLA-B, but not HLA-DB.[63] Interleukin (IL)-1α polymorphisms may also convey risk from juvenile DM for Caucasians.[64] A weak association may exist between an R620W variant of the *PTPN22* gene in juvenile idiopathic inflammatory myopathies.[65]

## Etiology and Pathogenesis

### Maternal Microchimerism

Juvenile DM has been postulated to resemble chronic graft-versus-host disease (GVHD), and maternally derived

chimeric cells have been found more often in children with juvenile DM than in either siblings or healthy controls.[66-69] These chimeric cells may be present in lymphoid aggregates in muscle tissue of affected children with juvenile DM, and chimeric stem cells may be seen in peripheral blood.[43,66] Studies in adult DM are lacking; interestingly, PM was seen in 8% of patients who underwent hematopoietic stem cell transplantation, in which 33% to 64% of patients develop chronic GVHD.[70]

### Infectious and Environmental Triggers

Many children will report symptoms consistent with infection before the development of juvenile DM; however, viral illness is common in this age group and retrospective analyses of infectious history before the development of juvenile DM is prone to recall bias. Multiple retrospective studies have been performed, indicating high frequency of infectious symptoms within a few months before onset. Searches for infectious agents in tissue or serum have been negative.[71,72] There has been some association of birth seasonality, especially in Hispanic patients, with risk of juvenile DM, but this was not reproduced in other ethnic groups within the same cohort.[73] Adult and juvenile DM also share a number of suspected environmental triggers that have been temporally associated with the onset of myositis, including exposure to excessive UV light, certain drugs (such as D-penicillamine), and infectious agents. A retrospective multicenter cross-sectional study in 2009 found that UV radiation intensity was associated with increased odds of adult DM compared with other inflammatory myopathies (odds ratio [OR], 2.3 [95% confidence interval [CI], 0.9 to 5.8]), and increased odds of anti–Mi-2 antibodies (OR, 6.0 [95% CI, 1.1 to 34.1]), and this effect was stronger in women.[74] A brief report in 2013 indicated that the highest UV index in the month before the development of symptoms was associated with development of juvenile DM versus polymyositis (PM), and development of anti-p155/140 antibodies.[75] There is also some evidence that maternal inhaled pollutants and tobacco exposure during fetal development may be associated with development of juvenile DM.[76]

## Clinical Features

Children with DM typically present with rash, proximal weakness, or both.

### Characteristic Rash

Typical rashes include a generalized photosensitive erythema, Gottron's papules, which occur over extensor

**Figure 108-5** Fifteen-year-old boy with newly diagnosed juvenile dermatomyositis demonstrating Gottron's papules over the metacarpophalangeal and proximal interphalangeal joints **(A),** heliotrope rash with periorbital swelling **(B),** and nailfold capillary dropout, dilatation, and tortuosity **(C). D** shows a 4-year-old boy with juvenile dermatomyositis with a cutaneous ulcer adjacent to his right axilla. He died 3 months after presentation.

surfaces (Figure 108-5A), and a periorbital heliotrope rash (Figure 108-5B). Multiple rashes have been described in adult and juvenile DM, but heliotrope rash and Gottron's papules are pathognomonic for DM. Adults may develop a thickened, erythematous, and scaly rash over the tips and lateral aspects of the fingers known as *mechanic's hands*; this occurs rarely in children. Evidence of small-vessel inflammation may be seen in the nailfolds, eyelids, and gums as telangiectasias of the capillary loops (Figure 108-5C). The number of end row nailfold loops can be quantified, and normal numbers of end-row loops in juvenile DM have been correlated with earlier diagnosis and less severe skin disease (Table 108-5).[77] Conversely, baseline nailfold abnormalities may predict slower time to improvement.[78] Persistent capillary abnormalities and Gottron's papules at age 6 months may also be associated with longer time to remission in children.[79] Severe vasculopathy may cause livedo reticularis and cutaneous ulcerations and may be an indicator of increased severity and poor prognosis; adults (4%) are less likely than children (24%) to develop ulceration.[80] Ulcerative lesions are more common over extensor surfaces and the inner canthi of the eye (Figure 108-5D).

### Proximal Muscle Weakness

Weakness is often insidious and difficult to recognize at onset. It is typically symmetric and affects proximal muscles. Parents may report fatigue and difficulty climbing stairs, combing hair, or getting out of bed rather than weakness. Children and toddlers may want to be carried more frequently. On examination, clinical weakness may be seen with difficulty performing sit-ups in school-aged children, development of head lag in a child after infancy, Gower's sign (use of hands on thighs to stand from a sitting position), or difficulty raising the arms straight above the head. Weakness may affect esophageal and respiratory muscles in severe cases. Respiratory weakness may lead to acute respiratory failure with hypercarbia rather than hypoxemia.

### Systemic Manifestations

Lipodystrophy and calcinosis are thought to be associated with long-standing or undertreated disease in juvenile DM and are uncommon in adults (see Table 108-5). Calcinosis may occur in as many as 40% of patients with juvenile DM; occasionally, it is found at the time of diagnosis but is typically thought to be a result of long-standing or severe disease.[81] An unusually high percentage of children with calcinosis (71%) was seen in a sub-Saharan African cohort, which was irrespective of time to diagnosis or use of steroids,[82] and there has been some suggestion that calcinosis may be more prevalent in African-American patients with juvenile DM.[83] Presence of calcinosis may predict higher disease activity in long-term follow-up.[84] Calcinosis may take several forms: superficial plaques and nodules, tumoral calcinosis, fascial plane deposition, or, rarely, an exoskeleton of calcium deposition (Figure 108-6).[85,86] Calcinosis may present with mixed forms as well. These lesions may be asymptomatic or may appear clinically similar to cellulitis with induration and erythema with pain, cause skin breakdown, or extrude calcium through the skin. Large deposits can impair function, cause contractures, or serve as a nidus for infection. These lesions are often associated with active ongoing disease, requiring aggressive treatment for the underlying condition.

Lipodystrophy has been reported in as many as 40% of patients, and may be localized, partial, or generalized. Subclinical lipodystrophy and metabolic abnormalities may be under-reported. Lipodystrophy clinically results in a progressive loss of subcutaneous and visceral fat and may be associated with a metabolic syndrome similar to polycystic ovarian syndrome, with insulin resistance, acanthosis, hypertriglyceridemia, and abnormal glucose tolerance.[87,88] Only a few cases of adults with myositis and lipodystrophy are reported in the literature (see Table 108-5).[89]

Fevers, dysphagia or dysphonia, arthritis, muscle tenderness, and fatigue are also commonly reported at diagnosis.

**TABLE 108-5** Clinical Characteristics of Juvenile Dermatomyositis (DM) and Adult DM

| | Juvenile DM | Adult DM |
|---|---|---|
| Peak age of onset | 7 years[48,55,54,51,56] | 30 to 50 years |
| Proportion of idiopathic inflammatory myositis cases | 80% to 95%[52,157] | 35% to 50%[157] |
| Proximal weakness | 85% to 95%[52,54,56] | 88%[158] |
| Characteristic rash | | |
| Gottron's papules | 73% to 91%[49,139] | 54%[158,159] |
| Heliotrope rash | 62% to 83% | 74% |
| Malar rash | 42% to 57% | N/A |
| Abnormal nailfold capillaries | 80% | 43% |
| Calcinosis or ulceration | 26% to 70%[80,82,139,160] | 2% to 16%[139] |
| Refractory or chronic disease | 59% to 63%[54,161] | 63%[160] |
| Mortality | <5%[54,80,160] | 21%[160] |
| Malignancy | 1%[54,160] | 15% to 24%[160,162] |
| Myositis-specific antibodies | 2% to 70%[90] | 40% to 80%[101,163] |
| Interstitial lung disease | 7% to 19%[90] | 35% to 40%[91] |
| Gastrointestinal disease | 2% to 3%[80] | 1%[80] |
| Raynaud's phenomenon | 10%[164] | 11%[165] |

N/A, Data unavailable.

**Figure 108-6** **A,** Elbow and forearm of a 14-year-old girl with chronic continuous juvenile dermatomyositis showing multiple sites of tumoral calcinosis. Several of these, particularly over pressure points, have ulcerated, extruding a chalklike material. **B,** Solitary site of tumoral calcinosis posterior to the knee resulted in limited range of motion. **C,** Fascial and tumoral calcinosis affecting the lower extremity. **D,** Same patient as in **A** demonstrating marked calcification, giving an exoskeleton-like appearance across the chest wall.

Rarely, vasculitis of the gastrointestinal (GI) tract with crampy abdominal pain, pancreatitis, GI bleeding, and potential for intestinal perforation or infarction may develop in patients.

### Lung Disease

Fatal pulmonary complications rarely develop in patients with juvenile DM. Interstitial lung disease (ILD) has been described in 7% to 19% (see Table 108-5).[90] In adults, ILD is a major contributor to morbidity and mortality in myositis, with ILD developing in 35% to 40% of patients during the course of their disease, associated with anti-synthetase antibodies such as anti–Jo-1.[91] Rapidly progressive ILD has also been associated with clinically amyopathic dermatomyositis and anti–CADM-140 autoantibodies.[92] Pulmonary function tests will show a restrictive pattern with decreased diffusing capacity for carbon monoxide (DLCO); high-resolution chest CT should be used for confirmation because pulmonary function test abnormalities may result from respiratory weakness alone. Imaging abnormalities include nodules, linear opacities, irregularity, ground-glass opacities, and fibrosis.

### Heart Disease

Involvement of the cardiac muscle with pericarditis, myocarditis, conduction defects, or heart block has been reported in patients. Cardiovascular complications in juvenile DM are rare (see Table 108-5). In a case-control study,

patients with juvenile DM had more evidence of diastolic dysfunction, pericarditis, and hypertension compared with healthy controls, although disease was largely subclinical.[93] More recent studies have implicated chronic inflammation in the pathogenesis of cardiovascular disease: Patients with adult dermatomyositis may have increased risk of acute myocardial infarction and ischemic stroke.[94] Given the fact that juvenile dermatomyositis involves chronic inflammation and, commonly, subclinical dyslipidemia and lipodystrophy, it would be logical to assume increased cardiovascular disease risk in this population, but this topic has not been well studied. One study has described evidence of increased endothelial dysfunction and worsened cardiovascular risk profile years after treatment of juvenile DM compared with healthy controls, despite decreased body mass index and younger age.[95]

### Amyotrophic Dermatomyositis

Some patients may be seen with classic rash of DM but no sign of muscle weakness or inflammation. This has been described clinically as *amyotrophic dermatomyositis* (CADM). In children, it is controversial whether these patients have mild undiagnosed muscle inflammation or will progress to more severe muscle involvement and/or long-term sequelae, such as calcinosis and lipodystrophy if untreated. There have been case reports of CADM associated with aggressive interstitial lung disease in Japanese children, and there may be some overlap with scleroderma.[96-99]

### Malignancy

An association with malignancy at disease onset is observed in adults with dermatomyositis but rarely in children (see Table 108-5).[100]

## Diagnosis and Diagnostic Tests

Elevated serum levels of muscle-derived enzymes (creatine kinase, aldolase, aspartate aminotransferase, and lactate dehydrogenase) reflect muscle inflammation or damage. In juvenile DM, elevation of creatine kinase becomes less sensitive as a marker with chronic disease. Evidence of ANAs is seen in more than 70% of juvenile DM.[101,102] However, myositis-specific antibodies are more prevalent in adults with DM and suggest a disease subset more than in juvenile DM. Recently, reports of new autoantibodies in juvenile DM may allow prediction of disease subsets. Lymphocyte enumeration may show an increased or decreased percentage of $CD19^+$ B cells via peripheral blood flow cytometry in juvenile DM or DM.[103,104] Neopterin and von Willebrand factor products have been reported to be elevated in a subset of patients with active inflammation from juvenile DM or vasculitis but are not specific for juvenile DM.[105,106] Because of the low sensitivity of the available laboratory testing, further gene expression, cytokine, and chemokine markers are under investigation.

Multiple studies have reported overexpression of type I IFN-regulated genes, cytokines (IL-6 and IL-1) and chemokines (IFN-inducible protein-10 [IP-10], monocyte chemoattractant protein [MCP-1], and myxovirus resistance protein [MRP-2]) in peripheral blood of adult and juvenile DM patients. These appear to be sensitive markers of disease activity and may differ between DM and juvenile DM.[107,108,109]

### Autoantibody Profiles

*Myositis-associated antibodies (MAAs):* ANA is present commonly in juvenile DM; however, tests for antibodies to SSA, SSB, Sm, RNP, and DNA are typically negative. MAAs (especially anti-SSA) are more commonly found in the adult population clinically thought to have DM. Antibodies to polymositis-scleroderma (PM-Scl) identify a small, distinct subgroup of myopathies with a protracted disease course, often complicated by pulmonary interstitial fibrosis and/or cardiac involvement as well as sclerodactyly. This subset in juvenile DM has many presenting features of scleroderma, such as severe Raynaud's phenomenon (RP). In adults, PM-Scl is associated with scleroderma myopathy and with cardiac involvement.

*Myositis-specific antibodies (MSAs):* MSAs are divided into three main groups: anti-synthetase antibodies, anti–signal recognition particle (anti-SRP) autoantibodies, and anti–Mi-2 autoantibodies. Each group has unique clinical features and outcomes. Anti-synthetase antibodies (anti-ARS, anti–Jo-1, anti–PL-12, anti–PL-7, anti-Ej, anti-Oj, anti-KS, anti-Ha, and anti-Za) have been associated with anti-synthetase syndrome, consisting of mechanic's hands, Raynaud's syndrome, ILD, arthritis, and fever.[110] Anti-synthetase antibodies are relatively rare in juvenile DM (2% to 4%). Anti–Mi-2 antibodies have been described in a low proportion of children with juvenile DM who typically have classic cutaneous juvenile DM rash with mild disease but elevated creatine kinase (CK) levels.[111] Recently, anti-p155/140 and anti-p140 autoantibodies have been described in 20% to 30% of children with juvenile DM.[112] The anti-p155/150 antibodies may be associated with extensive photosensitive skin rashes, capillary changes, ulceration, and lipodystrophy with chronic illness course. Anti-p140 antibodies may be associated with increased odds of calcinosis (OR, 7.0 [3.0 to 16.1]).[113] In adults, anti-p155/140 and anti-p155 autoantibodies may be associated with malignancy.[114] Another autoantibody, labeled *anti-MJ antibody*, also recognizes a 140 kDa protein and was associated with severe disease with contractures and atrophy in Argentinian children.[115] There is also an anti–CADM-140 autoantibody, which has been reported in Japanese patients with CADM who experienced rapidly progressive ILD.[92] It is unclear whether these autoantibodies target similar proteins or are epitopically distinct. Anti-SRP antibodies have been described in DM but are more commonly described with severe acquired necrotizing myopathies, which are refractory to treatment. The presence of MSAs is rare in children compared with adults; positive tests for anti–Jo-1, anti–Mi-2 and other MSAs may portend more significant disease. With increasing knowledge of new autoantibodies, currently, as many as 40% of children and 70% of adults may carry myositis-specific or -associated antibodies.[116]

### Muscle Pathology

Muscle biopsy is indicated particularly for an atypical presentation or when diagnosis is in doubt. The presentation

of clinical and muscle findings may be discordant, and recent evidence suggests a muscle biopsy may be useful for grading extent of disease and staging potential long-term severity.[117,118] Adult and juvenile DM are characterized pathologically by varying degrees of perifascicular atrophy, vasculopathy, and perivascular inflammation (composed predominantly of plasmacytoid dendritic cells [pDCs], B and $CD4^+$ T lymphocytes, and macrophages), focal necrosis and phagocytosis of muscle fibers, fiber regeneration, inflammatory cell infiltrates and vasculitis, and tubuloreticular inclusion bodies within endothelial cells. Evidence of vasculopathy includes muscle capillary thrombosis and deposition of complement and the membrane attack complex on muscle capillaries and reduction in number of and enlargement of remaining endomysial capillaries (capillary dropout). Capillary dropout has been found more prominently in areas of perifascicular atrophy, although capillary remnants may still be found in areas of endothelial cell loss.[119] Intermediate-sized vessels may also be affected. A Chinese study comparing muscle biopsies from adult and pediatric patients with DM found increased evidence of vasculopathy in pediatric biopsies compared with adults; this is also consistent with the descriptions from Bohan and Peter in 1975 and 1977.[120,121] Formation of neolymphoid structures in juvenile DM muscle, in which immature and mature $CD4^+$ T cells are seen with B cells and pDCs, suggest local maturation of T cells[122] structures were reported in adult DM with $CD4^+$ cells surrounded by B cells.[123] One of the earliest findings in adult and juvenile DM muscle tissue is the upregulation of class I major histocompatibility complex (MHC), which is almost universal in juvenile DM and, to a lesser extent, in adult DM. It is unclear whether the upregulation of class I MHC molecules is one of the precipitating events in myositis; however, animal models suggest a role in the unfolded protein response, which correlates with upregulation of IFN-β.[124]

In both juvenile and adult DM, the predominance of $CD4^+$ cells are not only $CD3^+$ (traditional $CD4^+$ cells); a subset are positive for CD123 and CD83 (markers for mature pDCs), and IL-17 staining, suggestive of T helper (Th)17 cells.[125-128] Increased frequency of Th17 cells have been reported in the peripheral blood mononuclear cells of adults with DM.[129]

Type 1 IFNs (IFN-α and IFN-β) are important in the pathogenesis of juvenile and adult DM. IFNs upregulate genes critical in immunoregulation and class I MHC expression, activate natural killer cells, support dendritic cell maturation, and promote the activation and survival of T cells. Muscle and skin biopsies in DM have shown increased pDCs and upregulation of IFN signaling.[130] It is thought that the class I MHC upregulation by IFN-α in myofibers may cause activation of the endoplasmic reticulum stress response in DM, which could lead to muscle-tissue injury and resulting myositis.[131] It has been shown that nucleic acid antibodies such as Ro/La and Sm/RNP can induce the production of IFN-α in children with juvenile DM.[132] Damage could also be caused by the cytokines upregulated by type 1 IFNs, including CXC chemokines (IP-10, MIG, and IFN-inducible T cell–α chemoattractant [I-TAC]). An anti–IFN-α antibody, sifalimumab, has been shown to neutralize IFN signature in patients with adult DM and PM, but larger-scale studies of its efficacy in this disease have not been conducted.[133] Tubuloreticular inclusion bodies are seen in DM and juvenile DM but rarely seen in other forms of myositis; they have been reported in circulating blood cells of other patients treated with IFN-α and in cultured endothelial cells in response to treatment with type I IFNs.[134,135,136] It is possible that these inclusion bodies may represent viral infection or increased IFN signaling.

### Peripheral Blood Phenotyping in Juvenile and Adult Dermatomyositis

Phenotyping of the peripheral immune blood cells, although not diagnostic, are dysregulated in a subset of individuals with juvenile DM and are proposed to be reflective of active disease. Untreated, early disease (<3 months) is suggested to have a lower B cell (CD20) numbers in the peripheral blood in both adult and juvenile DM; however, studies on recovery of these cells is lacking, and there are few data to suggest usefulness in monitoring of disease activity.[137,138] This is in contrast to adult DM, in which there are reports of total lymphocyte ($CD3^+$) decrease (CD19, CD4, CD8) before the onset of treatment, which recovers shortly after treatment. However, additional reports suggest that an increase of $CD19^+$ and $CD19^+CD23^+$ cells are seen, along with a decrease of $CD4^+CD45RO^+$ cells, are seen in the peripheral blood.[125]

## Differential Diagnosis

The most important differential diagnosis for patients seen with rash and muscle weakness is SLE, particularly for those patients seen with significant arthritis and a malar rash. Characteristic autoantibodies of SLE, cytopenias, renal disease, and hypocomplementemia help to differentiate these disorders. Patients with systemic sclerosis and prominent myositis may be difficult to differentiate from patients with JDM. Patients with mixed connective tissue disease and other overlap syndromes may have features of JDM in addition to those of other autoimmune connective tissue diseases.

Other idiopathic inflammatory myopathies are extremely rare in children. These include inclusion body myositis, granulomatous myositis, and macrophagic myofascitis.

Patients who are seen with either no rash or mild rash and predominant muscle weakness may need to be differentiated from patients with primary myopathies and muscle biopsy to help with the differentiation. Patients with muscular dystrophies often have positive family histories and an insidious onset of disease with characteristic muscle groups involved. Congenital myopathies usually are seen in infancy with hypotonia. Metabolic myopathies may be associated with developmental delay. Cramping and weakness after exertion may also be signs of metabolic myopathy.

Various infections may lead to an acute myositis. Perhaps the best recognized is influenza B, presenting with acute calf pain, weakness, and raised muscle enzyme levels. *Trichinella* infection may be associated with periorbital edema and significant peripheral eosinophilia. Many other bacteria, viruses, and parasites may cause myositis; they should be suspected in the appropriate clinical circumstance.

**TABLE 108-6** Treatment of Juvenile Dermatomyositis (DM)

## Treatment

### Traditional Therapies

Standard medications to treat juvenile DM are shown in Table 108-6. However, there have been no prospective case-control double-blinded studies of immunosuppressive therapy in juvenile DM. After the inception of corticosteroid treatment of juvenile DM, the mortality rate decreased markedly compared with historic controls. Prolonged corticosteroid treatment is associated with significant morbidity, including decreased height velocity in children, weight gain, osteoporosis, immunosuppression, avascular necrosis, adrenal suppression, cataracts, diabetes, and more. With the use of MTX in juvenile DM, the mean time of corticosteroid use was 10 months compared with historic controls who were treated for a mean time of 27 months.[139] Surveys of North American pediatric rheumatologists indicate that most practitioners will treat typical juvenile DM with CSs and MTX, although there is great discrepancy between dosing regimens. Adjunct medications and medications for refractory disease vary but include hydroxychloroquine, intravenous immunoglobulin, rituximab, cyclophosphamide, cyclosporine A, azathioprine, tacrolimus, and MMF.[140] In a North American registry of juvenile DM patients, almost all subjects were treated at some point with MTX (7.5 to 15 mg/m$^2$ or 1 mg/kg to a max of 40 mg weekly) and CSs; approximately 50% had been treated with hydroxychloroquine or intravenous immunoglobulin (IVIG).[51] In a large cohort of European and South American patients with juvenile DM, European patients were more likely to receive cyclophosphamide, cyclosporine, and azathioprine as treatment, suggesting some cultural or national variations in prescribing practices.[56]

In adults, CSs and multiple immunosuppressive agents have been used for treatment of DM and PM. In retrospective studies, MTX has been postulated to be effective as a steroid-sparing agent, but comparisons with other immunosuppressive agents have shown no superiority. A randomized trial of azathioprine versus MTX in adults showed no significant difference in effect.[141] Similarly, a randomized controlled trial of cyclosporine A versus MTX showed no difference in efficacy or toxicity.[142] MTX and azathioprine have also been tried in combination.[143] There has been no evidence that MTX is associated with ILD in adult DM, but this may be a rationale for the increased use of azathioprine in adults compared with children.

### Therapy for Refractory Disease

In open-label studies, IVIG has been helpful for patients with refractory disease and may help decrease steroid toxicity and improve skin and muscle disease, but placebo-controlled trials of this are not available in children.[144] In adults, a double-blind placebo-controlled trial showed improvement in skin and muscle disease, with improvement in biopsy results after treatment.[145] IVIG may help with severe dysphagia and esophageal weakness in adults.[146] Adverse reactions in juvenile DM patients have been associated with the IgA content in IVIG infusions.[147] In retrospective studies, MMF has been used as a steroid-sparing agent and may benefit patients with refractory skin and muscle disease.[148,149] Similarly, cyclosporine has been reported to have beneficial results on juvenile DM in small case series.[150,151] A pilot study of etanercept in patients with refractory juvenile DM showed no appreciable improvement.[152] There is no specific evidence basis for treatment of calcinosis, although multiple case reports of various treatments have been reported, but it is felt that control of disease activity is important in controlling calcinosis. Anti-TNF agents, bisphosphonates, and calcium channel blockers have been used for this purpose. Surgical excision may be indicated in areas of recurrent infection, chronic pain, or impedance of function from calcinosis. Treatment of resistant skin disease is controversial: Topical CSs and pimecrolimus may help with symptomatic itching or redness, but it is possible that resistant skin disease reflects ongoing systemic disease and should be treated with increasing immunosuppression.

Biologic therapies are beginning to emerge for the treatment of myositis, and given the findings of increased serum CD19$^+$ B cells and lymphoid follicles in muscle biopsies of affected patients, rituximab has been proposed as a possible therapy. Initial case series noted clinical improvements in skin and muscle that paralleled B cell depletion.[153] A large randomized controlled crossover trial of rituximab in refractory juvenile DM and adult DM/PM (the Rituximab in Myositis Study) was conducted. All patients received rituximab, and the outcome was time to response. The study found 83% of refractory adult and juvenile patients with myositis met the definition of improvement, but there was no significant difference in time to improvement.[154] Subanalysis of this group suggests that there may be better response to rituximab in the juvenile cohort within this study.[155]

### Consensus Protocols

CARRA has developed consensus protocols for therapy of patients with moderately severe juvenile DM, which include

combinations of oral CSs, pulse IV CSs, MTX, and IVIG.[156] Within the CARRA Registry cohort, almost all patients have been treated with CSs, and approximately half have been exposed to pulse CSs or IVIG.[51] Use of consensus protocols with time will hopefully lead to a more evidence-based rationale for treatment in the future.

### Outcome

In children, prognosis is generally favorable, although work needs to be done in minimizing treatment toxicity and long-term morbidities of disease (calcinosis, lipodystrophy, cardiac, and pulmonary complications). Patients may follow one of three disease courses: monocyclic, polycyclic (flares of disease while off treatment), or chronic continuous disease. Delay in recognition or undertreatment may result in prolongation of disease course. In the modern era, two large series showed that 40% of patients pursued a monophasic course, and the remainder followed a polycyclic or chronic continuous course.[84,156]

### Conclusion

Although the causes of juvenile DM are still elusive, recent developments point to the involvement of IFN and lymphoid follicles in the pathogenesis of DM. International and national collaborators are working on developing standard protocols for assessment and treatment of juvenile DM. An initially aggressive approach with CSs and disease-modifying anti-rheumatic drugs (DMARDs) such as MTX may result in better long-term outcomes and less calcinosis and steroid toxicity. Work in using IFN and cytokine signaling as a biomarker and using findings in pathogenesis as a rational basis for treatment and therapy will be a challenge for dermatomyositis researchers in the future.

## PEDIATRIC SCLERODERMA: SYSTEMIC AND LOCALIZED FORMS

**KEY POINTS**

- **Pediatric scleroderma includes two different clinical phenotypes: systemic sclerosis (SSc) and localized scleroderma (LS). Despite clinical differences, both share a common pathophysiology, with an initial inflammatory phase associated with endothelial activation and a later fibrotic phase evident by collagenization of the tissue and appreciable skin thickness.**
- **Juvenile SSc (jSSc) has similar subtypes and organ manifestations compared with adult-onset SSc, except that there is an increased frequency of overlap SSc and associated antibodies and clinical features, such as arthritis and myositis.**
- **Despite similar organ involvement and manifestations, survival rates in jSSc are substantially higher in jSSc than SSc.**
- **Although LS is typically limited to the skin and underlying connective tissue, at least one-quarter of the patients have extracutaneous manifestations, especially those with linear scleroderma of the extremities or head.**
- **Both SSc and LS are best treated systemically if identified during the earlier inflammatory stage when progression can be halted, whereas advancement is still needed in developing anti-fibrotic therapy to help reverse disease damage.**

The scleroderma disorders in children encompass both systemic sclerosis (SSc) and localized scleroderma (LS), also termed "morphea." In childhood-onset scleroderma, SSc is much less common than LS and comprises less than 10% of all SSc cases.[166,167] Both share the general features of an earlier inflammatory state, followed by collagen deposition and atrophy. Skin biopsies of these patients are typically indistinguishable, and they may share some common pathophysiology; however, their clinical manifestations are markedly different with unique morbidities and prognoses. LS is typically confined to the skin and underlying tissue, and although without the fatal potential of SSc, as many as a quarter of the patients may have extracutaneous disease manifestations, such as joint contractures and uveitis.[168] Although any organ may be affected in SSc, vascular (RP), cutaneous (skin thickening), GI, pulmonary, and musculoskeletal involvement are most commonly seen in children. Both SSc and LS can be further classified by subtype (Table 108-7; see Table 108-11).

### Epidemiology

Both conditions are uncommon in children; the estimated annual incidence of LS is 1 to 3.4 per 100,000 children[169,170] and of SSc is 0.27 to 1 per million children.[169,171] The mean age of onset for both forms of pediatric scleroderma is between 7 and 9 years of age. Unfortunately, there is significant delay in diagnosis, with an average of 0.7 to 2.8 years for SSc[166,167,169,172] and 0.9 to 1.6 years for LS.[168,172,173] For the few cases of congenital involvement of LS, the mean time to diagnosis is longer, 3.3 to 3.9 years.[173,174] The approximate female to male ratio of pediatric SSc is 4:1,[166,167] and for pediatric LS it is 2:1. There is no clear evidence for racial predilection for either form of pediatric scleroderma.

### Genetics

Genetic studies are lacking in pediatric-onset SSc and LS, although some HLA investigations are currently underway. Familial history of autoimmune disease, as in other connective tissue diseases, is not uncommon in either LS or SSc, with a general range of 10% to 25% positive family history of first-degree relative with conditions such as psoriasis, RA, SLE, Sjögren's syndrome, thyroiditis and, less commonly, SSc and LS.[167,168,173,175]

### Pathogenesis (Shared Between LS and SSc)

The skin histology findings of these two conditions are indistinguishable. Mononuclear cell populations identified in both SSc and LS skin specimens are predominantly T cells, both CD4 (Th) and $CD8^+$.[176,177] Th cell–associated cytokines and chemokines, such as IL-2, -4, -6, -8, -13, and TNF, have been identified in the circulating sera and

**TABLE 108-7** Clinical Subtypes of Systemic Sclerosis (SSc)

| Subtype | MAIN CLINICAL FEATURES | | Antibody Association |
|---|---|---|---|
| | Organ System | Organ System Features | |
| Diffuse cutaneous (dc) | Skin | Thickness proximal to elbows and knees<br>Rapid progressive thickening | Topoisomerase (Scl-70) |
| | Cardiac | Congestive heart failure<br>Conduction abnormalities | |
| | Renal | Scleroderma renal crisis | |

CTD, Connective tissue disease; DM, dermatomyositis; PM-Scl, polymyositis-scleroderma antibody; SLE, systemic lupus erythematosus; U1-RNP, U1 ribonucleoprotein antibody.

stimulated peripheral blood mononuclear cells (PBMCs) from LS and SSc patients.[178-183] Other chemokines, such as those associated with the IFN-γ pathway and suggest a Th1 profile—CXCL-10 and MCP-1—have been associated with both LS and SSc.[184,185] These T cell–associated chemokines and cytokines in turn further stimulate fibroblasts and endothelial cells to produce TGF-β and connective tissue growth factor (CTGF), which are thought to be the main stimulators of tissue fibrosis (via increased collagen production) and endothelial cell damage (via influence of adhesion molecules ICAM-1 [intercellular adhesion molecule-1] and VCAM-1 [vascular cell adhesion molecule-1]).[186-189]

The Th and regulatory T cell (Treg) immunophenotypes of patients with jSSc have been recently reported by Reiff and colleagues[190] and demonstrate some similarities and differences with adult-onset SSc. Both SSc[191] and jSSc demonstrate a decrease in Treg population while disease duration increases, and the chemokine receptor, CCR7, has increased RNA expression on both,[192] although only patients with jSSc have increased expression on the surface of T lymphocytes.[190] In jSSc there was an increase in frequency of the CD45RA-expressing effector memory T cell subpopulation,[190] but not in SSc studies.[193] Some of these differences may be attributable to reduced thymic function, with defective thymopoiesis in jSSc.[194]

Microchimerism is another area of interest under investigation regarding a shared pathogenesis between LS and SSc. Clinically and histologically, LS and SSc share characteristics with chronic GVHD, also termed *sclerodermatous GVHD*, a condition in which microchimerism plays a role in pathogenesis. Chimeric cells have been identified in patients with LS and SSc by using real-time polymerase chain reaction (PCR) techniques.[195,196]

## Systemic Sclerosis

### Classification

The three main subtypes of SSc—diffuse cutaneous (dc), limited cutaneous (lc), and overlap syndrome—which are present in adult-onset SSc, occur in pediatric-onset SSc with similar organ manifestations and antibodies associated with these subtypes (see Table 108-7). However, there are some differences in distribution of clinical subtype and associated antibodies between adult and pediatric patients (Table 108-8). There are only a few "large" cohort studies evaluating jSSc,[166,167,197-199] and in those that included the evaluation of overlap syndromes,[198] it is apparent that this subtype constitutes a significant proportion (approximately one-third) of patients with jSSc. The antibodies associated with overlap syndrome, PM-Scl and U1-RNP, and their affiliated clinical features of myositis and arthritis are more commonly observed in jSSc.[166] Another main difference is the lack of anti-centromere antibody–positive patients with jSSc (≤5%),[166,198,199] especially with pre-pubertal patients (<10 years at onset).[199] This is true despite approximately 30% to 50% of patients with jSSc classified as lcSSc (see Table 108-8). Because of some of these differences and the more indolent onset of symptoms in jSSc, provisional classification criteria were developed for jSSc to enable detection of early disease, such as the inclusion of positive ANA, Raynaud's phenomenon, and nailfold capillaroscopy changes. These criteria were developed through international efforts among PRES (Pediatric Rheumatology European Society), European League against Rheumatism (EULAR), the ACR through the Delphi survey, and nominal group techniques[200] and are displayed in Table 108-9. Some patients with undifferentiated or mixed connective tissue disease may have shiny or full-appearing

skin of the distal fingers, but they must have the major criterion, "skin induration or sclerosis proximal to the metacarpophalangeal (MCP) or metatarsophalangeal (MTP)," in addition to two minor criteria, to be classified with jSSc (see Table 108-9).[200]

## Clinical Features

Please refer to Chapter 84 for detailed organ manifestations in SSc. Here we will emphasize the similarities and differences between childhood-onset SSc and SSc.

In general, larger cohort studies of juvenile-onset SSc have been followed up into adulthood and compared with adult-onset SSc cohorts in that geographic region to compare disease course, organ complications, and outcome. The four largest studies are summarized in Table 108-10 and support similar frequency of the main SSc organ manifestations, such as ILD and pulmonary arterial hypertension (PAH), but there are differences with increased musculoskeletal involvement (because of overlap prominence in jSSc) and less scleroderma renal crisis in juvenile-onset SSc.[166,167,198,199] Despite this, jSSc was found to have significantly better survival rates compared with adult-onset SSc in these cohort studies.

### Vascular Manifestations

Common features at the onset of jSSc are RP (70%) and skin changes of hands (60%), including edema, sclerodactyly and induration proximal to the MCPs (Figure 108-7).[167] In the largest cohort of pediatric SSc (153 patients) studied, 53% presented with both skin induration of hands and RP, and 10% of those presenting with RP also had digital infarcts.[167] Throughout the course of the disease, almost all will have RP (97%) and skin changes of the hands (96%),

Data from references 166, 167, 198, and 199.

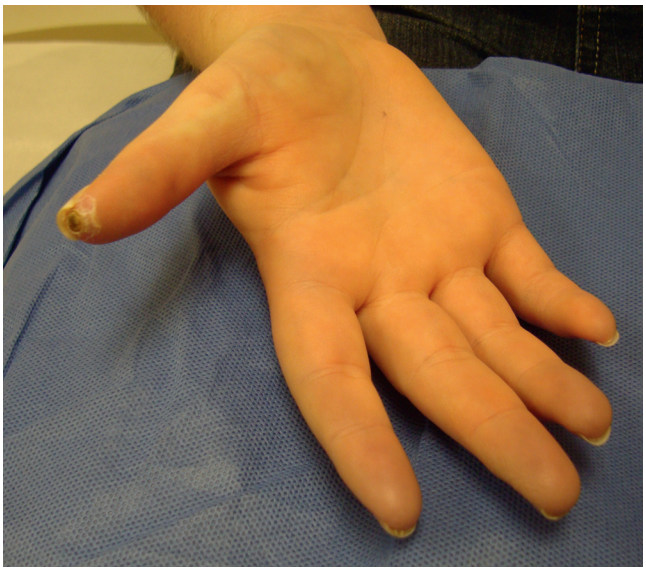

**Figure 108-8** Patient with overlap systemic sclerosis (polymositis-scleroderma positive) with several years of Raynaud's phenomenon. A digital nonhealing ulcer has developed on her thumb and has bluish discoloration of distal fingers secondary to moderate-severe Raynaud's phenomenon.

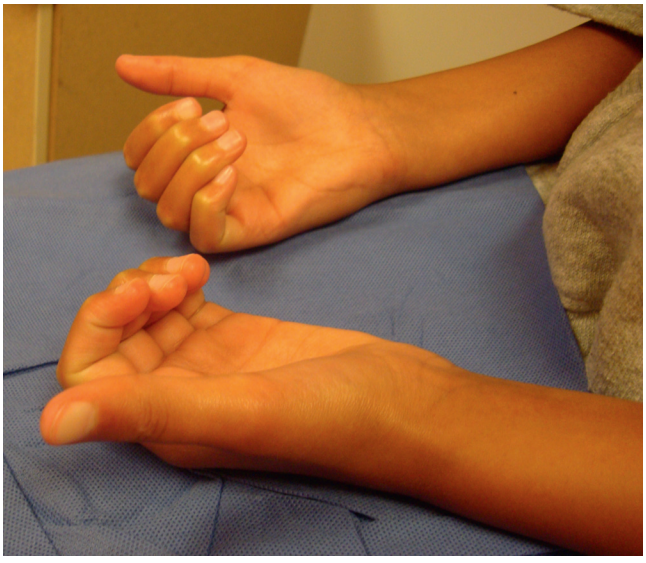

**Figure 108-9** Maximum finger flexion in a patient with juvenile systemic sclerosis with diffuse cutaneous disease (scleroderma-70 positive). Overlying skin thickening and deeper collagen infiltration of the tendons causes finger joint contracture with both limited flexion and extension.

and digital ulcers will develop in approximately one-third (Figure 108-8; Table 108-10).[166,167,198,199] Nailfold capillaroscopy changes, including dilatation, tortuosity, hemorrhage, drop-off (avascularization) and, later, arborization of the capillaries,[201] are observed in children as they are in adult SSc, and, if identified in context with RP, should raise suspicion for diagnosis of jSSc. The prevalence of nailfold capillary changes in jSSc is reported to be 50%[166,167] but is likely higher if standardized microscopy is performed.

### Cutaneous Manifestations

Cutaneous manifestations are similar to adult-onset SSc, in which there is an edematous, sclerodactyly phase with associated increase in skin thickness (see Figure 108-7), followed by an atrophic phase. There is a distal tapering of fingers, with some jSSc having shortened middle and distal phalanges and loss of digital pads in adulthood.[166] Joint contractures, especially of the hands, are common in jSSc due to overlying skin and deep tendon collagen deposition and tightening (see Figure 108-9; see Table 108-10). The typical scleroderma facies of tight atrophic skin produces a pinched nose, thin pursed lips, small mouth, and prominent teeth occurs in children but may be less dramatic. Skin thickness is measured using the modified Rodnan Skin Score (mRSS),[202] and in general mirrors that found in adult-onset SSc (see Table 108-10).[199] Other skin findings in jSSc include those found in adult-onset SSc, such as subcutaneous calcium deposits (calcinosis cutis) and telangiectasias.

Other organ manifestations in jSSc (in order of decreasing frequency) include GI, pulmonary, musculoskeletal, cardiac, renal, and neurologic symptoms (see Table 108-10).

### Gastrointestinal Manifestations

GI symptoms occur in approximately half of the children, although more detailed investigation often indicates the presence of abnormalities in a larger percentage.[166] Esophageal dysmotility and gastroesophageal reflux often leads to dysphagia and esophagitis, and also increases the risk of aspiration pneumonia. Gastroparesis with delayed gastric emptying, in addition to esophageal dysfunction, can lead to increased reflux symptoms. Evaluation of the GI tract by using manometry and intraesophageal 24-hour pH monitoring have been reported as sensitive indicators of lowered esophageal tone and reflux.[203] However, these modalities are used less often in pediatrics. Instead, a swallow study with speech therapy and radiology to evaluate for aspiration and dysmotility, followed by an upper GI study with small bowel follow-through (SBFT), are typically used. If the small bowel is involved, cramps, diarrhea, and constipation may result from peristaltic dysfunction. Episodes of pseudo-obstruction with post-prandial abdominal distension, pain, and nausea can occur because of a functional ileus. Bacterial overgrowth, steatorrhea, weight loss, volvulus, and, even perforation, can occur.

### Pulmonary Involvement

Pulmonary involvement in jSSc ranges from 30% of 70% in the literature and includes ILD, PAH, and abnormal pulmonary function tests (PFTs). PFT abnormalities especially of concern are decreased forced vital capacity (FVC) and DLCO.[204] The clinical presentation of ILD with slowly progressive dyspnea on exertion (DOE) and that of PAH with a more rapid progression of DOE is similar between adults and children with SSc. Moderate to severe lung disease from progressive pulmonary fibrosis appears to be less frequent in children, with 9% and 13% of the patients with jSSc having an FVC less than 50% in two large cohorts.[166,198]

### Musculoskeletal Involvement

Compared with adult-onset SSc, musculoskeletal involvement is more common in pediatric SSc. Approximately one-third of patients with jSSc experience inflammatory arthritis (joint effusions) in addition to the typical dry synovitis of scleroderma, reflected by the fibrosis of tendons transversing the joints, which limits their range of motion (ROM).[166,167] Early in the disease process, especially in those with dcSSc, tenosynovitis/bursitis causes palpable tendon friction rubs (a "leathery crepitus") when the joint is extended or flexed,[205] demonstrated in approximately 10% of patients with jSSc.[167,199] Myopathy typically results in symmetric proximal weakness and muscular atrophy. Muscle weakness has been reported to range between 20% to 32% in jSSc cohorts (see Table 108-10),[166,167,199] and was markedly higher than the adult comparison cohort in one of the studies.[166] Myositis also occurs, more commonly in the overlap SSc subtype, and presents similarly juvenile DM. Children with dcSSc and myositis are particularly at risk for severe cardiac involvement, including myocardial perfusion deficits and dilated cardiomyopathy.[206]

### Cardiac Involvement

Cardiac involvement, although infrequent (see Table 108-10), is the major cause of scleroderma-related mortality in children, as evidenced by 10 out of 15 deaths in the Martini and colleagues cohort[167] and 5 out of 32 in the Scalapino and colleagues cohort.[166] Cardiac manifestations result from the combination of myocardial fibrosis, vascular insufficiency, and inflammation and include heart block, arrhythmia, congestive heart failure, cardiomyopathy, and pericarditis. In contrast to pediatric SSc, scleroderma-related mortality in adults is primarily caused by pulmonary involvement, both ILD and PAH.[207]

### Renal Dysfunction

Mild renal dysfunction is not uncommon in SSc and is secondary to vasculopathy instead of glomerulonephritis and occurs with similar frequency in jSSc and SSc. In contrast, the more severe and morbid form of renal disease, scleroderma renal crisis (SRC), occurs in approximately 15% of adult patients with SSc but only rarely in children (<5%, only five patients among the four cohorts).[166,167,198,199] SRC is characterized by accelerated arterial hypertension, renal insufficiency, microangiopathic hemolytic anemia, and thrombocytopenia. SRC is most frequently seen early in disease course of dcSSc RNA polymerase III-positive patients, which is an antibody rarely detected in jSSc (see Table 108-8), possibly explaining the low frequency of SRC in jSSc.

### Neurologic Involvement

Neurologic involvement in jSSc is rare (<5% in all studies) and can include CNS changes, such as seizure, abnormal brain MRI findings, and peripheral neuropathy.[167]

## Diagnosis and Diagnostic Tests

The diagnosis of jSSc relies on distinctive clinical features (see Table 108-9), and subtypes are further defined by both skin thickening distribution and scleroderma-related serum autoantibody profiles, which predict organ involvement in both adult- and childhood-onset SSc (see Table 108-7).[166,167,197,208,209] See Tables 108-7 and 108-8 for antibody relationship to clinical features and disease subtype. Although many scleroderma-related autoantibodies have been identified in adult SSc, there is a high proportion of pediatric patients (20% to 23%) who have a positive ANA without a specific autoantibody identified.[166,197]

### Evaluation/Disease Monitoring of the Patient with jSSc

For most children with SSc or suspected SSc, initial cardiopulmonary assessment, especially evaluating for evidence of ILD and PAH, includes chest radiograph, PFTs with DLCO, electrocardiogram, and an echocardiogram. For pediatric patients, it is important that the DLCO is calculated by using a specific pediatric mean predictive DLCO based on the patient's weight, height, age, sex, and race. This will avoid the unwanted anxiety of a falsely low reading if unmatched norms are used. Additional cardiopulmonary

testing is pursued if abnormalities are detected or the patient is too young to appropriately complete testing (i.e., PFTs). Abnormal PFTs prompt evaluation with high-resolution computed tomography (HRCT) of the chest and, possibly, bronchoalveolar lavage (BAL) if further evidence of inflammation (alveolitis) is required or evaluation of infection is needed before starting therapy.[204,210] Evidence of PAH on echocardiogram, elevated right-side-of-the-heart pressures, is more formally assessed by right-heart catheterization as in adults. A 6-minute walk test may also be used, but the standardized values in children are still being determined and depend on ethnicity, weight, height, and age, and nonpulmonary issues may contribute to decreased values, such as musculoskeletal involvement.[211,212] After initial assessment, ongoing cardiopulmonary screening with an annual echocardiogram and quarterly to twice a year PFTs with DLCO are recommended by most pediatric rheumatologists, at least in the first few years of disease.[210] There is a lack of consensus regarding screening for GI involvement in jSSc. Most practitioners will screen at some point in time for evidence of silent aspiration and dysmotility with a swallow study and upper GI with SBFT; additional imaging is more dependent on symptoms (see discussion under GI symptoms above).

There are no standardized biomarkers available, although a study has suggested serum KL-6, a mucin-like protein strongly expressed in type II pneumocytes, as a promising noninvasive pulmonary marker of fibrosis in jSSc.[213]

## Treatment

Treatment of SSc is dependent on organ involvement, but general measures such as antacid medication for GI protection, prokinetic agents for dysmotility, rotating antibiotics for malabsorption, as well as vasodilators for RP (may also help with PAH), NSAIDs and physical therapy (PT) for arthritis or tendonitis are generally recommended. CSs for myositis, arthritis, and other inflammatory clinical features must be used with caution because they can prompt SRC. More specific treatment recommendations for different organ manifestations have been agreed upon by a consensus conference of international scleroderma experts and should be considered for all patients with SSc.[214] The reader is referred to Chapter 84 for a more in-depth discussion of SSc treatment. As in adult SSc, autologous stem cell transplant is an option and may be the best opportunity for survival in selected severe patients, with a number of successful outcomes reported.[215]

## Outcome

Despite all the potential organ involvement in pediatric SSc, it has a far more favorable prognosis at 5, 10, and 15 years compared with adult SSc, with a lower frequency of severe organ involvement. Foeldevari and colleagues[198] recently reported Kaplan-Meier survival rates at 10 years for children to be 98% versus 75% in adults. In jSSc cohorts, the most common cause of death was cardiac (including PAH) and respiratory failure.[166,167,197] Death within a few years of onset of disease (majority ≤5 years) was reported in two jSSc cohorts.[167] Martini and coleagues proposed a model for prediction of poor outcome in jSSc that included fibrosis on chest radiograph, raised creatinine levels, and pericarditis.[216]

More recently, the research group at Padua University coordinated a study that developed and validated the jSS Severity Score (J4S), to objectively establish the degree of jSSc severity in daily practice using a comprehensive score.[217] This is not a mortality predictor but a gauge to possibly use longitudinally to follow the patients' disease course and trajectory, and will enable comparisons of patients across observational cohorts and assist in the stratification of patients for clinical trials. It is mirrored from the Medsger Severity Score,[218] ranging from normal, mild, moderate, to severe involvement of different organ manifestations and general health parameters. The J4S is a promising measure and should be validated in prospective studies.

## Localized Scleroderma

### Classification

Localized scleroderma (LS) has a different pattern of skin involvement than systemic sclerosis (SSc) and encompasses several subtypes classified by depth and pattern of the lesion distribution. The group of disorders is characterized by fibrosis and atrophy that is mainly confined to the skin and subcutaneous tissue; however, deeper forms also involve the fascia, muscle, tendon, and joint capsule. Certain subtypes of LS have unique associated extracutaneous manifestations (ECMs). The "Padua criteria" have been used more recently to describe the LS subtypes, which include a "mixed morphea" subtype; the prevalence of this category is 15% in juvenile LS (jLS) (Table 108-11).[219] The most common subtype in jLS is linear scleroderma (LiScl) (50% to 60%), which is characterized by a linear streak or band involving the dermis, subcutis, and often the underlying muscle, tendons, and bone. LiScl typically occurs as a single, linear, unilateral band on the extremities, trunk, or head.[168,173] Linear lesions crossing the joint may cause joint contracture and limb dysfunction (Figure 108-10A). Of particular concern in pediatric patients with LiScl is involvement of the underlying tissues, including muscle, bones, growth plates, and organs, which can lead to permanent shortening or atrophy of the limb (Figure 108-10B). Orthopedic complications are reported in approximately 30% to 50% of patients with LiScl of the limb(s), causing mild to moderate disability.[170,173,220,221]

Linear lesions affecting the head affect approximately 25% of patients with jLS.[168] Those with more obvious cutaneous findings, displayed as a dyspigmented linear streak or depression of the scalp and forehead, are termed "en coup de sabre" (ECDS), resembling a saber wound scar (Figure 108-11). Those with more atrophy of the subcutis, with associated hemifacial atrophy of the mandible, maxilla, tongue, and muscle tissue of the face are classified with Parry-Romberg syndrome (PRS). These disorders can occur together, either at the same location (side of face) or opposing sides (Figure 108-12).[222] PRS and ECDS are associated with neurologic, ophthalmologic, and dental ECMs. Neurologic involvement is demonstrated in 8% to 20% of the patients with these conditions, including CNS involvement expressed as seizures, chronic headaches, optic neuritis, and, less frequently, neuropsychiatric changes or ischemic

**TABLE 108-11** Proposed Subtypes for Juvenile Localized Scleroderma: Padua Preliminary Classification*

| | |
|---|---|
| Circumscribed morphea | Oval/round lesions<br>(a) Superficial lesions (*Plaque morphea*)—limited to epidermis and dermis<br>(b) Deep lesions (*Deep morphea*)—involve subcutaneous tissue |
| Linear scleroderma | Linear lesions can involve dermis, subcutaneous tissue, muscle, bone<br>(a) Trunk/limbs<br>(b) Head-*En coup de sabre* or *Parry-Romberg syndrome* |
| Generalized morphea | ≥4 large plaques (>3cm) on at least 2 of 7 anatomic areas: head/neck, Right upper extremity, LUE, RLE, LLE, anterior trunk, posterior trunk |
| Pansclerotic morphea | Circumferential involvement of limb (spares fingertips/toes)<br>All depths skin/subcutaneous tissue/muscle/bone |
| Mixed morphea | Combination of two or more of above subtypes |

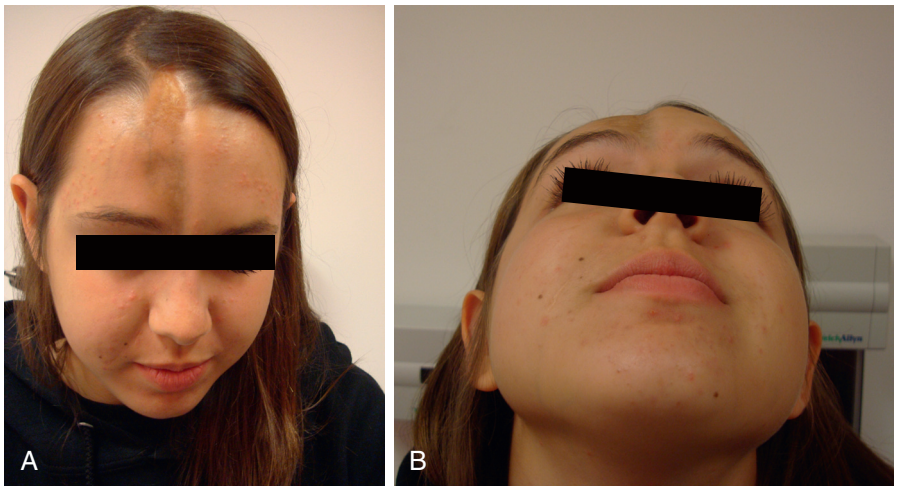

**Figure 108-11** Pediatric patients with localized scleroderma with typical "sword of the saber," or "en coup de sabre" lesion affecting the forehead and scalp with resultant skull depression.

**Figure 108-12** Patient with long-standing juvenile localized scleroderma, linear scleroderma of the head, both en coup de sabre variant (affecting the right lower face) and Parry-Romberg subtype (left hemifacial atrophy). She also has hemitongue atrophy, skewed palate, malocclusion, and other dental abnormalities.

stroke.[222,223] Orthodontic (i.e., malocclusion) and ophthalmologic (i.e., uveitis) abnormalities also have been reported with similar prevalence in both conditions.[223]

The less common subtypes of jLS are superficial and deep circumscribed LS, generalized morphea and pansclerotic morphea. Most superficial circumscribed lesions (epidermis and upper dermal involvement) affect the trunk, are more common in adults, and are usually treated topically (do not come to rheumatology attention). Deep circumscribed morphea affects the dermis and subcutis with variable penetration into the fascia and muscle. Typically, there are only subtle cutaneous changes, such as slight erythema and thinning of the dermis, but secondary to deep infiltrate causes a scooped-out appearance of the subcutis. Generalized morphea (GM) is more typical in the adult LS population, occurring in less than 10% of patients with jLS,[168,173] and is associated with systemic symptoms such as myalgia, arthralgia, and fatigue.[173,175] Lesions typically are widespread throughout the trunk and coalesce. This subtype is often associated with several autoimmune phenomena, including positive antibodies and concomitant and family history of autoimmune disorders.[175] Although pansclerotic morphea is a rare subset of LS, affecting 1% to 2% of patients, it is the most disabling. It initially involves the extremities but later may migrate to the trunk, only sparing the face and distal areas of fingers and toes (Figure 108-13). There is a rapidly progressive fibrosis of the deep dermis, subcutis, fascia, and muscles, with occasional bone involvement. This leads to significant contracture of joints, muscle atrophy, cutaneous ulcerations and sometimes restrictive pattern of respiratory insufficiency if the truck is involved. The development of squamous cell carcinoma is an additional complication in pansclerotic morphea, especially in areas of chronic wounds.

Eosinophilic fasciitis (EF), once considered a type of deep morphea by Peterson criteria, is not considered a subtype of jLS by Padua criteria, although it often behaves as a mixture of deep morphea and linear scleroderma, resulting in deep infiltration and joint contractures, and is treated the same as LS.[224]

**Figure 108-13** Pansclerotic morphea subtype affecting bilateral upper and lower extremities and some of this patient's trunk, only sparing the face and very distal finger and toe skin. There is notable atrophy of the subcutis and muscles as well as diffuse joint contractures.

## Clinical Features

### Cutaneous Manifestations

**Disease Activity and Damage Features: Clinical and Histologic Findings.** Similar to SSc both clinically and histologically, LS exhibits an earlier more active phase of disease and a later, more fibrotic, phase. Early active lesions in LS are characterized by a violaceous inflammatory border or "lilac ring" and skin induration throughout the lesion that may appear waxy or white (Figure 108-14). During this active state, lesions may also expand and new lesions can accumulate.[225] Histologic findings in the early stages of disease consist of a perivascular and perineural infiltrate of predominantly lymphocytes with admixed rare plasma cells and eosinophils in the deep reticular dermis and subcutis, accompanied by thickened collagen bundles, decreased elastic fibers, and swollen endothelial cells.[226-228] With time, disease damage accumulates and is represented by an increase in skin thickness, especially at the center of the lesion, combined with dermal and subcutaneous atrophy,

**Figure 108-14** Typical active inflammatory localized scleroderma lesion with white, waxy center and violaceous halo ("lilac ring").

appearing as visible veins, "cliff drop" appearance of the dermis, and flattening or concavity of the subcutis, respectively. Histologic evaluation of the skin at this stage reveals thickened hypocellular (homogenized) collagen that replaced the previous inflammatory infiltrate around the dermal appendages, leaving behind atrophic eccrine glands and hair follicles. In addition, capillaries are decreased in number with a fibrotic wall and narrowed lumen.[226,227] Post-inflammatory hyperpigmentation and hypo-pigmentation also are a result of previous inflammation and are often the features that bring the lesion to the attention of a medical provider.

**Extracutaneous Manifestations.** ECMs are not uncommon in LS and occur in approximately one-quarter of the patients throughout the course of disease.[229] According to a large international study of 750 children with LS, ECMs are more frequent in patients with LiScl and consist essentially of orthopedic complications (19% in the entire group, 50% in those with LiScl of the extremity), and neurologic or ocular findings (24 patients, 5% in the entire group, 60% in those with LiScl of the head).[229] Less common ECMs are GI, respiratory, and renal, all of which occurred in less than 2% of the 750 patients examined.[229] These estimates may be lower than the true percentage of ECMs, because only symptomatic patients were included in the analysis. Interestingly, of the 168 patients with ECMs, 25% had articular, neurologic, and ocular manifestations unrelated to the site of skin lesions, further supporting the hypothesis that localized scleroderma is more of a systemic process.[229]

## Diagnosis and Diagnostic Tests

**Diagnosis.** LS remains a clinical diagnosis by physical examination features, and when there is uncertainty, a skin biopsy is supportive (findings described in previous text). There are no diagnostic laboratory tests for LS, but there is a high prevalence of autoantibodies, including ANA, anti-histone antibody (AHA), and anti–single-stranded DNA antibody (ssDNA Ab), which could be supportive of the diagnosis.[230] A positive ANA is found in 42% to 73% of patients with LS and has been associated with an increased risk for ECMs.[229,231] The prevalence of ssDNA and AHA in LS is approximately 50%[180,232] and both are associated with disease severity features, such as deep muscle involvement, joint contractures, and increased number of lesions.[221,230,231] In addition, RF is present in one-third of patients, particularly those who have GM, and also correlates to disease severity (number of lesions).[168] These antibodies (ssDNA and AHA) and RF may help in stratifying patients during the earlier stages of disease, suggesting the possible initiation of more aggressive therapy and increased surveillance.

General markers of inflammation, including erythrocyte sedimentation rate (ESR) and serum immunoglobulin levels (IgG and IgE), may be useful markers of disease activity in select patients with LS, particularly those with deep or eosinophilic-like variants. However, the majority of patients seen with active LS lesions do not have elevation of these markers. A recent review of the CARRA Registry data of 259 patients with jLS supports elevated creatine phosphokinase (CPK) or aldolase to reflect disease activity through their association with new lesions. CPK elevation was also associated with muscle atrophy and limb shortening and may predict muscle involvement.[233]

Differential diagnosis is limited and includes lichen sclerosus et atrophicus and atrophoderma of Pasini and Pierini; superficial dermal and epidermal inflammatory conditions that are thought by some to be on the milder spectrum of LS; cutaneous T cell lymphoma, especially if there is a deeper purple skin discoloration; and collagenoma, usually presenting with induration of the skin and subcutis without pigmentary changes. Other possible conditions are associated with certain exposures and generally have more widespread lesions, such as GVHD (status, post-transplant), nephrogenic fibrosing dermatopathy (gadolinium administered in renal compromised state), and porphyria cutanea tarda (sun exposure).

**Diagnostic Tests.** Several tools have been used for the assessment of skin and subcutaneous involvement in LS, such as clinical skin scores, measurement tools, and imaging. Clinical skin scores are commonly used by physicians and include the modified Rodnan Skin Score[202] and the Localized Scleroderma Cutaneous Assessment Tool (LoSCAT), which combines disease activity and damage parameters.[225,234] A computerized skin score (CSS) can be used to determine the size of lesion in an objective manner.[235] Measurement tools, including a durometer, which measures the degree of skin hardness,[236] and a cutometer, which measures skin elasticity,[237] have also been proposed as useful. In addition, several types of imaging can be used for diagnostic or assessment purposes, such as thermography,[238,239] laser Doppler flowmetry,[240] ultrasound,[241,242] and MRI.[243] Some of these techniques have been validated in LS, including the LoSCAT, the CSS, ultrasound using higher frequencies (10 to 25 MHz), and MRI. However, currently, standard measures are not widely used, and assessment depends on center-specific modalities that rely on the investigator's experience. Recent efforts through CARRA used expert opinion to outline clinical criteria for the assessment of disease activity, damage, and severity features of LS, which include cutaneous, laboratory, and imaging features, to stratify patients and monitor disease status as they enter a consensus treatment plan (CTP).[244]

In general, there is not any recommended internal organ screening for a patient with LS because they tend not to have typical SSc features; however, the exception is LiScl of the head. A baseline brain MRI, ophthalmology examination, and dental evaluation are considered standard by experts in the field.[212] Because of the high incidence of odontostomatologic abnormalities in LiScl of the head, a recent study suggests cone-beam CT as a useful technique to evaluate and monitor hard and soft tissue changes.[245]

### Treatment

Approach to the treatment of LS initially depends on the severity of the disease, which is characterized by the subtype of LS, potential involvement of deeper tissue and structures (such as joints), location of LS, and disease activity state. If the diagnosis has been significantly delayed and only disease damage parameters remain, simply monitoring the lesion is acceptable. However, if there is any sign of active disease, such as erythema or lesion expansion, both rheumatologists and dermatologists agree treatment is warranted. For a single superficial circumscribed lesion in a noncosmetically concerning location, topical treatment with CSs, calcineurin inhibitors, imiquimod, vitamin D, or recurrent phototherapy with UV light is acceptable. All modalities have had clinical success in case series or uncontrolled trials exhibited by lightening of hyperpigmentation and decreased skin thickness. UVA-1 was successful in two randomized control trials, especially in regard to early inflammatory and superficial dermal lesions.[246,247] There is growing consensus among both rheumatologists and dermatologists that systemic therapy is warranted for more moderate to severe LS, which is defined as lesions with deep tissue involvement (subcutis, fascia, and muscle) that transverse a joint and potentially cause functional impairment, affect the face or scalp, are rapidly progressive or widespread active disease, and for those who have failed topical or UV therapy.[248,249] The most commonly used systemic therapy is MTX in conjunction with CSs.[249]

The first double-blind randomized control trial in jLS with objective measures was performed by Zulian and colleagues comparing MTX and oral CS versus placebo and oral CS. MTX was found to be effective and safe, confirming the community's support for the use of MTX in LS. In addition, those treated with MTX significantly improved and had significantly fewer relapses compared with those on CS alone.[250] An open-label extension (average follow-up, 40 months) supported continued MTX efficacy, with 74% responders and 73% maintaining remission after weaning off of medications.[251] Relapses were documented during this longitudinal study, and the authors concluded that is beneficial to continue MTX treatment for at least 24 months to ensure a prolonged and sustained disease remission.[251] This was supported in a retrospective study, reporting higher relapse rates in those with shorter MTX treatment duration.[252]

A subcommittee of CARRA derived four CTPs for the first 12 months of induction of therapy for those with moderate to severe jLS. Three protocols involve subcutaneous MTX (1 mg/kg, with a maximum dose of 25 mg/week), and the fourth was derived for those who either fail to respond to MTX or are intolerant to MTX. The protocols are divided into MTX alone, MTX with oral CS and taper, MTX with IV CS, and MMF in addition to either oral or IV CS.[244] MMF was included as an alternative because it has been shown to be effective in severe MTX-resistant jLS (panscleroticc, GM, LiSCl subtypes).[253] Patients have been enrolled into the juvenile LS CTP and data collection, and analysis is currently ongoing.

**Other Therapies.** Intensive physical and occupational therapy in conjunction with systemic immunosuppressive therapy is recommended for those with linear or deep scleroderma of the extremity to help minimize joint contractures. Also, for those with ECDS and/or PRS, plastic surgery intervention is felt to be reasonable after the disease has been in remission without any signs of clinical activity. Augmentation includes fat grafting with microdroplets from the patient's abdominal subcutis to assist in filling in some of the subcutaneous atrophy to yield a more symmetric facial contour. For more severe disease, fasciocutaneous flaps and facial bone reconstruction are also options, although they are typically reserved for the late teenage years after the skeleton has matured.[254]

### Outcome

The largest obstacle to good outcomes is awareness of LS among primary care physicians, and timely referral to academic dermatology or rheumatology to enable correct diagnosis and treatment while the disease is still in active phase. Once months or years have passed and fibrosis and atrophy dominate, current therapies that target inflammation have little usefulness. Two recent European studies demonstrated an average 11- to 13-month delay from onset to correct diagnosis of LS.[172,255] In one of the studies, all 50 cases were originally misdiagnosed or undiagnosed at first provider visit.[255] A North American dermatology longitudinal morphea cohort confirmed that prolonged interval between onset and definitive diagnosis adversely affects the final outcome.[172,256]

Once systemic immunosuppressive therapy is initiated in patients with moderate to severe LS, the signs of disease activity typically resolve within months, and some of the damage features mildly to moderately improve.[250,252,257-260] After this initial improvement, the detection of subclinical disease is important so as to not wean off of immunosuppression too early, potentially resulting in relapse.[250,257,260] In general, it is recommended to treat for 2 to 3 years with MTX with continued remission before stopping systemic therapy. After this initial course, it is not uncommon for the patient to relapse, and despite prior notions that LS "burns out," approximately one-third of patients will relapse, requiring reinitiation of systemic therapy. In the author's opinion, theses relapses occur in the same region or at the site of the original lesion, and most respond to reinitiation of systemic therapy.

## Conclusion: LS and SSc

Although the underlying pathogenesis of jLS and jSSc remain understudied and mostly rely on adult SSc studies, newer data are available, suggesting a shared immunophenotype and associated cytokine profiles between juvenile

and adult patients and between LS and SSc. Treatment is most effective during the active inflammatory state in both jLS and jSSc; therefore it is imperative to raise awareness to general providers for prompt referral, diagnosis, and management. CARRA is further refining disease activity, damage, and responsiveness measures of LS through consensus treatment plans to offer more defined guidelines for therapy management and to be used in future clinical trials of LS. The J4S is a promising tool for similar purposes in jSSc.

# PEDIATRIC VASCULITIS

**KEY POINTS**

- **Henoch-Schönlein and Kawasaki disease represent the majority of childhood vasculitis, following a self-limited course in the majority of children with excellent outcomes when recognized and treated appropriately.**
- **Specific pediatric criteria for diagnosing several of the vasculitides more commonly seen in adult populations have been defined.**
- **Primary CNS vasculitis of childhood has modified diagnostic criteria and unique categories of disease compared with adult populations.**
- **Prompt recognition and initiation of therapy are essential and can result in remarkable recovery.**

Childhood vasculitis encompasses a broad spectrum of diseases, from predominantly self-limited disease to chronic, progressive disease with devastating end-organ damage. Pediatric vasculitis is defined similarly to adult vasculitides with disease categories based on the size and distribution of vessel involvement as well as histology. They can be associated with infection, medication exposure, and other systemic disease. Although the incidence of the vasculitic subtypes varies across patient populations and ethnicity, the overall incidence of childhood vasculitis is 23/100,000, with Henoch-Schönlein (HSP) and Kawasaki's disease (KD) representing the majority of cases.[261] Although other forms of childhood vasculitis are rare, they tend to be more chronic, with a greater potential for significant morbidity.

A classification system for childhood vasculitis takes into account vasculitic conditions predominantly seen in children and reflects the clinical features particular to pediatric populations.[262] This section will focus on the types most commonly seen in the pediatric age range and highlight the unique features of childhood-onset vasculitis.

## Small-Vessel Vasculitis: Henoch-Schönlein Purpura

### Definition and Classification

HSP, the most common pediatric vasculitis, is characterized by an IgA-mediated leukocytoclastic vasculitis.[263] Self-limited in most cases, it is associated with significant morbidity in a notable minority who experience persistent renal impairment and end-stage renal disease.

### Epidemiology

HSP has an incidence of 10 to 20 per 100,000 children and affects boys more commonly than girls.[261,264-266] The highest incidence is seen in young children, with a population study reporting an incidence of 70 per 100,000 children aged 4 to 6 years.[261] HSP is much less common in adult populations but may be associated with more aggressive disease.[267,268]

### Etiology and Pathogenesis

Infectious triggers have long been recognized, with more than half of affected children having a preceding upper respiratory infection.[269] IgA is thought to play a pivotal role in the pathogenesis of HSP, with $IgA_1$ found to complex with IgG and deposit in the kidney.[270] IgA-bound streptococcal M protein deposits have been found in the skin and kidneys of patients with HSP, serving as a link between infection and vasculitis.[271]

### Clinical Features

Nonthrombocytopenic purpuric skin lesions are the hallmark of HSP, and their presence is required for the diagnosis.[265,266,272] Palpable purpura and petechiae appear predominantly over the lower extremities and in dependent areas. The rash may initially manifest as a maculopapular or urticarial rash before evolving into the more classic purpura, and may even progress to areas of necrosis. Lesions are seen in various stages and sizes during the course of the disease, often occurring in waves, with skin manifestations lasting 4 to 8 weeks.[266,272]

Arthritis and arthralgias are common, reported in approximately 60% to 75% of cases.[265,266,272] The arthritis is usually painful, nonerosive, and nonmigratory. Periarticular swelling, without clear arthritis, is also well described. Knees and ankles are the most frequently affected joints, although wrists and small joints of the hands may also be involved. Scrotal swelling and swelling of the hands and feet are commonly seen, especially in children younger than 2 years of age.[272]

GI symptoms occur in 50% to 75% of children, manifesting predominantly as abdominal pain.[265,266,272] The pain can be quite severe and may be seen before the characteristic rash appears. This complicates the diagnosis, and these children may initially undergo evaluations for appendicitis or other GI diseases. Occult GI bleeding may occur; although gross bleeding and intussusception are rare, they pose significant morbidity.

Renal disease is described in 40% to 50% of children with HSP.[265,266,272,273] Although it is most often mild and self-limited, it is the major cause of morbidity and requires careful follow-up. The majority of cases involve microscopic hematuria or low-grade proteinuria presenting in the first 6 weeks, with only a 2% risk of developing nephritis more than 2 months after diagnosis.[273-276] Nephrotic-range proteinuria or nephritis will develop in some children, with older children having potentially higher rates of nephritis.[275] Renal biopsies performed in those with marked renal disease demonstrate IgA nephropathy. The degree of damage on biopsy as well as higher levels of proteinuria confer a

worse outcome.[277] End-stage renal disease develops in 1% to 3% of children with HSP.[272,278,279]

### Diagnosis and Diagnostic Tests

There are no specific diagnostic markers of HSP, and the diagnosis is largely made on clinical features.[263] Elevated sedimentation rates (57%), elevated serum IgA (37%), and proteinuria (42%) are the most common laboratory abnormalities.[265,266,272,273] Urinalysis should be obtained serially in all children given the potential for developing nephritis with time. Skin biopsy may be performed to confirm the diagnosis but is not required in most cases. Skin biopsy demonstrates a leukocytoclastic vasculitis with IgA deposition.[277] Stool guaiac and imaging should be considered in those with abdominal complaints to evaluate for GI bleeding and intussusception.

### Treatment

Treatment recommendations vary depending on the severity of disease. Most children with HSP have self-limited disease that requires only supportive care, including hydration, NSAIDs (use with caution if significant GI complaints are present), and pain management.[280] For those with more severe disease, there are no clear treatment recommendations. Prednisone has been found to reduce abdominal pain and arthritis symptoms, but there is no indication it reduces purpura or prevents the progression of nephritis.[274,281-283] The largest benefit from CSs seems to be in preventing the GI complications of HSP, with fewer abdominal surgeries and endoscopies.[282] For children with more severe disease, particularly nephritis, high-dose IV pulse methylprednisolone, azathioprine, and cyclophosphamide are at times used, although there are no clear recommendations for immunosuppressive therapy.[284]

### Outcomes/Prognosis

Overall, the majority of children with HSP have a self-limited disease resolving within 4 to 6 weeks, with only 1% to 3% progressing to end-stage renal disease.[277] Of patients in whom nephritis develops during their course, 30% will have some degree of ongoing renal impairment. Recurrence is commonly seen, affecting a third of children, especially in those older than 8 years and those with nephritis.[265,274,276,278,279] More persistent disease will develop in some children, and they will require a chronic DMARD to control their disease.

## Medium-Vessel Vasculitis: Kawasaki's Disease

KD is the second most prevalent form of pediatric vasculitis. It is frequently triggered by an infectious or proposed environmental exposures.[261,285,286] First described as infantile polyarteritis nodosa based on histologic findings, KD is now recognized as a distinct disease with characteristic clinical and laboratory features.[287] Although KD is a monophasic, self-limited inflammatory condition, the cardiac complications are the leading cause of acquired heart disease in childhood in Western countries.[288-290]

### Classification

The diagnosis of KD is made based on clinical features, with supporting laboratory and imaging studies (Table 108-12). Since initially described, a spectrum of disease with fewer than four criteria, with or without cardiac involvement, has been recognized and termed "incomplete" or "atypical" KD.[288,291] In 2004, the American Heart Association proposed an algorithm to assist in the diagnosis of incomplete KD (see Figure 108-15) that was subsequently found to increase the detection of KD.[292-294]

### Epidemiology

KD is predominantly seen in young children, with the majority (80%) of cases in those between 1 and 5 years of age. Males are affected more frequently than females, with reported ratios of 1.4 to 1.9:1.[285,288] Incomplete disease is more common in children younger than 1 year and older than 9 years of age, with as many as one-third of children in these age groups seen with incomplete disease. Incidence rates vary greatly across ethnicity; Asian children have the highest rates, with 218/100,000 in children younger than 5 years in Japan and 113/100,000 in Korea, compared with 5 to 13/100,000 in Western countries.[285,288,295,296] Genetic variation in pro-inflammatory genes and matrix metalloproteinases are thought to play a role in susceptibility and disease severity.[297,298]

### Clinical Features

KD progresses through three phases: acute (as long as 14 days), subacute (2 to 4 weeks), and convalescent (as long as several months). The acute phase is characterized by high fever, ocular findings, and rash. Continuous, high-grade fever is the hallmark of KD but is less consistently seen in children younger than 1 year and older than 9 years. By definition, the fever should last at least 5 days and be minimally responsive to anti-pyretics.[292] Ocular manifestations include nonpurulent conjunctivitis with limbic sparing (more than 90% of cases) and asymptomatic uveitis. Rashes are reported in more than 90% of cases, and although nonspecific, commonly affect the perineal area and axilla in the acute phase of the disease. The characteristic sheetlike desquamation described in KD starting at the fingertips is seen in the subacute phase and after the period of maximal benefit from IVIG. Mucocutaneous changes include marked erythematous, swollen and cracked lips, strawberry tongue and, less frequently, oral ulcers. Hands and feet often appear swollen. Cervical lymphadenopathy is the least common of the five classification criteria, and is asymmetric with a single lymph node greater than 1.5 cm.[285,288,292,299] Although not a classification criterion, neurologic manifestations are common, including irritability, lethargy, headaches, and aseptic meningitis. Nondestructive polyarticular or oligoarticular arthritis, dysuria, sterile pyuria, scrotal pain, abdominal pain, hydrops of the gallbladder, and diarrhea are also well described in children with KD. Macrophage activation syndrome has been described as a complication.[300]

Cardiac disease can be seen as myocarditis, pericarditis, and/or endocarditis. The most concerning feature of KD is

**TABLE 108-12** Classification Criteria of Pediatric Vasculitis

| | Required Criteria | Additional Criteria |
|---|---|---|
| **Small-Vessel Vasculitis** | | |
| Henoch-Schönlein purpura | Purpura or petechial with lower limb predominance plus one additional criteria | 1. Arthritis/arthralgia<br>2. Abdominal pain<br>3. Histopathology with IgA deposition<br>4. Renal involvement (hematuria or proteinuria) |
| **ANCA-Associated** | | |
| Granulomatous polyarteritis | No required criteria; need 3 of 6 criteria | 1. Histopathologic evidence of granulomatous inflammation<br>2. Upper airway involvement<br>3. Laryngotracheal-bronchial involvement<br>4. Pulmonary involvement (radiograph or CT)<br>5. Positive ANCA<br>6. Renal involvement (proteinuria, hematuria, necrotizing pausi-immune glomerulonephritis |
| **Medium-Vessel Vasculitis** | | |
| Kawasaki's disease | Fever for ≥5 days plus 4 of the additional criteria | 1. Bilateral conjunctivitis (nonpurulent)<br>2. Changes in the lips or oral cavity<br>3. Cervical lymphadenopathy<br>4. Polymorphous exanthema<br>5. Changes in peripheral extremities/perineal area |
| Polyarteritis nodosa | Systemic inflammation with biopsy evidence of necrotizing vasculitis or angiographic abnormalities of medium sized arteries plus at least one of the additional criteria | 1. Skin involvement (livedo reticularis, modules, infarcts)<br>2. Myalgia/muscle tenderness<br>3. Hypertension (>95th percentile)<br>4. Peripheral neuropathy<br>5. Renal involvement (proteinuria, hematuria, impaired function) |
| **Large-Vessel Vasculitis** | | |
| Takayasu's arteritis | Characteristic angiographic abnormality of the aorta or its major branches and the pulmonary artery plus one of the additional criteria | 1. Absent peripheral pulses or claudication<br>2. Blood pressure discrepancy in any limb<br>3. Bruit<br>4. Hypertension(>95th percentile)<br>5. Increased acute phase reactants (ESR >20, any elevation in CRP) |

ANCA, Anti-neutrophil cytoplasm antibody; CT, computed tomography; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; Ig, immunoglobulin.
Modified from Ozen S, et al: EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II: Final classification criteria. *Ann Rheum Dis* 69:798–806, 2010.

coronary artery disease that results in the majority of morbidity and mortality. The coronary changes tend to appear in the subacute and convalescent stages, although they can be seen in the acute stage, and include dilatation, ectasia, and frank aneurysms.[285,288,292,299,301]

## Diagnosis and Diagnostic Tests

Characteristic laboratory studies include elevated inflammatory parameter, with markedly elevated sedimentation rates (ESR) and C-reactive protein (CRP) (Table 108-13). Complete blood counts reveal elevated white blood cells and platelets. Platelets are usually markedly elevated, often more than a million, but low platelets can also be seen and indicate higher risk for coronary disease.[302] Hemoglobin is usually low, even at onset of disease. Urinalysis may reveal sterile pyuria caused by urethritis. Mild elevations in alanine aminotransferase (ALT) and low albumin are commonly seen.[285,288,292,299,301] A high level of suspicion is needed to ensure those with possible incomplete KD are evaluated per the current recommendations (Figure 108-15). Infectious studies should be performed, given the association with infectious triggers, but it is important to recognize KD can develop in the setting of infections, and a concurrent infection does not preclude the need to treat patients who meet the clinical and laboratory criteria for KD with IVIG and other recommended therapies while also treating active infections.[286]

**TABLE 108-13** Laboratory Findings in Acute Kawasaki's Disease

| |
|---|
| Leukocytosis with neutrophilia that can be immature forms |
| Elevated erythrocyte sedimentation rate and C-reactive protein |
| Thrombocytosis after 7+ days |
| Anemia |
| Elevated plasma lipids |
| Hypoalbuminemia |
| Hyponatremia |
| Sterile pyuria |
| Elevated serum transaminases and gamma-glutamyl transferase |
| Pleocytosis of cerebrospinal fluid |
| White cell elevation in synovial fluid if arthritis |

An echocardiogram should be performed at diagnosis, after 2 weeks, and again at 6 weeks. ECG should be done at presentation. Abdominal ultrasound should be considered for those with abdominal pain and evaluation of hydrops of the gallbladder. The American Heart Association guidelines should be referenced to evaluate for incomplete disease and prognostic indicators.[292] Given that macrophage activation syndrome has been described in some children with KD, additional studies, including ferritin, triglycerides,

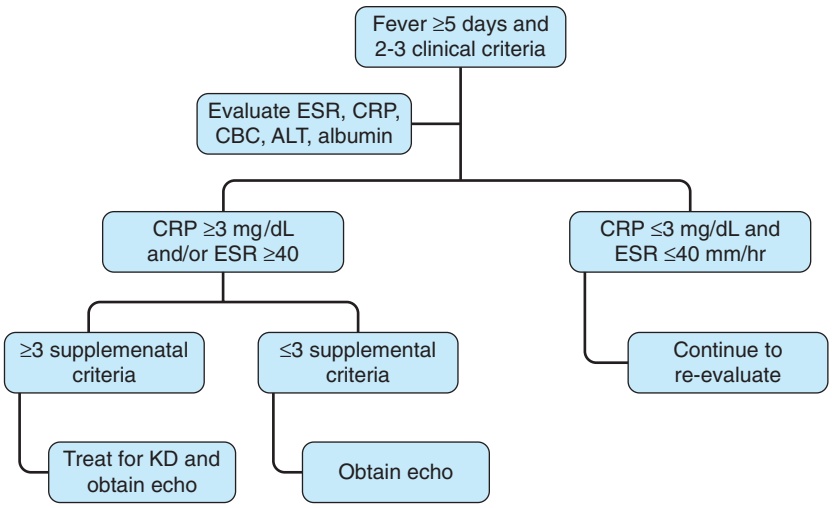

**Figure 108-15** Evaluation of incomplete Kawasaki's disease (KD). Supplemental criteria: albumin 3.0 g/dL or less, anemia for age, elevated alanine aminotransferase (ALT), platelet count 450,000 or higher after 7 days of illness, white blood cell (WBC) count 15,000 or higher, urine with higher than 10 WBC/high-powered field. CBC, Complete blood cell count; CRP, C-reactive protein; echo, echocardiogram; ESR, erythrocyte sedimentation rate. *(Modified from Newburger JW, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association.* Pediatrics *114:1708-1733, 2004.)*

fibrinogen, and D-dimers, should be considered in children with more severe disease.[303]

### Treatment

IVIG and aspirin are considered first-line therapy for the treatment of KD.[288,290,292] Studies have demonstrated a dose-dependent response to IVIG, with dosing of 2 gm/kg given during 12 hours having greater efficacy than both lower-dose IVIG and divided doses.[304] High-dose aspirin (80 to 100 mg/kg) is recommended until the patient becomes afebrile. Low-dose aspirin should be continued at 3 to 5 mg/kg until the 6-week repeat echocardiogram and normalization of the platelet count.[292] However, it should be noted that the evidence for the use of aspirin is limited.[305,306]

Incomplete response to IVIG with persistent or recurrent fevers or continued elevation of CRP is common and should be treated with a second course of IVIG.[307-310] Patients with continued refractory disease may be treated with steroids or infliximab.[311,312] A recent study reported no added benefit of adding methylprednisolone to the initial dose of IVIG.[313] TNF is noted to be elevated in patients with KD and thought to be an important mediator of disease. Infliximab has shown improved efficacy versus repeated doses of IVIG for children with continued refractory disease, although there are no data to support infliximab as first-line therapy.[309,312,314]

### Outcome

Overall, the 5-year survival rate is 99%, although coronary artery damage will develop in 1 in 20 children, including aneurysms and stenosis.[315,316] In addition, although the long-term impact of transient coronary dilatation is unclear, there is concern for potential endothelial dysfunction and early atherosclerosis, and these children require ongoing follow-up.[317-321]

## Anti-neutrophil Cytoplasm Antibody–Associated Vasculitis, Polyarteritis Nodosa, and Takayasu's Arteritis

### Definition and Classification

Other forms of pediatric vasculitis are rare and present with similar manifestations as adult-onset disease.[262,322-326] Given the paucity of these vasculitides in children, much of the information on pathophysiology, clinical manifestations, and treatment is based on adult studies. This section will highlight some of the differences between adult and pediatric disease. Please refer to the individual chapters on each disease for more in-depth review.

## Anti-neutrophil Cytoplasm Antibody-Associated Vasculitis

### Epidemiology

Anti-neutrophil cytoplasm antibody (ANCA)-associated vasculitis is a small-vessel necrotizing vasculitis and includes granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome). Overall, these are very rare conditions in the pediatric population, with GPA the most prevalent.[262,322-327] The EULAR/PRES-endorsed criteria are listed in Table 108-6. Given the paucity of both MPA and eosinophilic

granulomatosis with polyangiitis in children, there are no pediatric-specific classification criteria.

### Clinical Features

The clinical features of the various ANCA-associated vasculitic conditions overlap significantly and predominately involve the kidneys, lungs, and upper airway. Mean duration from onset of symptoms to diagnosis is approximately 2 months in children. Constitutional symptoms with fever, fatigue, and weight loss are seen in the majority of cases, with renal and pulmonary involvement seen in more than 80%.[262,322-329] Upper airway disease, including sinusitis, mastoiditis, subglottic stenosis, and nasal septum perforations are common in children and may be a more prominent feature than in adult disease, as is an increase in thrombosis.[323,330,331]

### Diagnosis and Diagnostic Tests

Laboratory studies are similar to adults. ANCA is positive in the majority of children, with 66% having a positive cytoplasmic (c)ANCA and 22% a positive perinuclear (p)ANCA (Table 108-14).[323,330] A positive test for proteinase 3 (PR3) antibodies and a positive cANCA are seen primarily in patients with active granulomatosis with polyangiitis. Positive MPO antibodies and pANCA are seen primarily in microscopic polyangiitis but also are reported in glomerulonephritis, eosinophilic granulomatosis with polyangiitis, and Goodpasture syndrome. MPO and pANCA may be seen in other autoimmune disorders, such as Sjögren syndrome, systemic lupus erythematosus, and rheumatoid arthritis as well as (rarely) in nonrheumatic disease.

### Treatment

Treatments for childhood-onset disease are largely based on adult studies and include cyclophosphamide, B cell–depleting agents, high-dose CSs and, at times, plasmapheresis, as well as MTX and azathioprine for maintenance or milder disease. The use of B cell–depleting therapies provides promise for those with refractory disease and recurrent disease, with more recent studies suggesting use as first-line therapy for systemic disease.[322,332-334] ANCA-associated vasculitis has a chronic, relapsing-remitting pattern in children, similar to adult disease.

**TABLE 108-14** ANCA Antibodies and Disease Classification

| | Patients with cANCA and PR3 | Patients with pANCA and MPO |
|---|---|---|
| Granulomatosis with polyangiitis | 90% inactive disease, 60%-70% inactive disease | Less than 10% |
| Microscopic polyangiitis | 30% | 60% |
| Eosinophilic granulomatosis with polyangiitis | Rare | 50%-80% |

ANCA, Anti-neutrophil cytoplasm antibody; cANCA, cytoplasmic ANCA; MPO, myeloperoxidase; pANCA, perinuclear ANCA; PR3, proteinase 3.

## Polyarteritis Nodosa

### Classification

Polyarteritis nodosa (PAN) is the third most prevalent pediatric vasculitis, although it only affects 3% to 6% of children with vasculitis.[335-337]

The diagnostic criteria for pediatric systemic PAN was modified by the EULAR/PRES consensus group to require biopsy evidence of necrotizing vasculitis or angiographic abnormalities (see Table 108-12).[262] Overall, cutaneous PAN is believed to be more common and characterized by periodic flares often associated with streptococcal infections.[335,338]

### Clinical Features

The clinical features are similar to adult-onset disease, with systemic manifestations of inflammation, including fever, weight loss, fatigue and malaise, classic skin findings of painful subcutaneous nodules tracking along vessels, as well as abdominal pain, neuropathy, and hypertension.[335-337,339-342]

### Diagnostic Testing and Treatment

The diagnostic evaluation and treatment mirror adult disease as well, with the use of CSs, azathioprine, MTX, biologics (anti-TNF and B cell–depleting therapy), and cyclophosphamide all reported.[334,335,342,343] Prophylactic antibiotics should also be considered if streptococcal infection was a trigger. There are limited data on the long-term survival of children, with reports of 5-year survival rates across populations of 60% to 90%.[340,342,344,345]

## Takayasu's Arteritis

### Classification and Epidemiology

Takayasu's arteritis (TA) is the most prevalent large-vessel vasculitis in children.[346] Pediatric diagnostic criteria require angiographic abnormalities as listed in Table 108-12.[262,338,347-351] Although rates of TA are so low the incidence and prevalence in children are not known, children in Africa, Asia, and Latin America seem to be at increased risk. The association with *Mycobacterium tuberculosis* may play a role in some of the differences seen across populations.[347-349,352-356]

### Clinical Features

As with other forms of systemic vasculitis, children with TA are seen with constitutional symptoms as well as signs of organ ischemia. Headaches, strokes, chest and abdominal pain, and claudication are common complaints.[354,357,358] Cardiovascular evaluations may reveal hypertension, absent pulses, and bruits. Arterial wall disease can manifest as vessel wall thickening, stenosis, occlusion, or even aneurysms. Conventional angiography provides information on distribution of vessels involved, perfusion, collateralization, and stenosis. Doppler ultrasound correlates well with angiogram in many children and may be a useful modality especially for follow up.[359-362] Children are more likely to experience aneurysms than adults (41% vs. 11%), although

given the fact that aneurysms frequently heal with fibrosis, there is a lower risk of rupture.[363]

### Treatment and Outcome

Treatment is similar to adults, with a broad range of agents used, including high-dose CSs, cyclophosphamide, MTX, TNF inhibitors, and IL-6 inhibitors.[355,356,364-366] Although the overall survival for TA is 70% to 93%, children may have lower rates of remission than adults (24% compared with 56%) and have significant limitations and morbidity.[315,363,367,368]

## Central Nervous System Vasculitis

CNS vasculitis can affect small and medium vessels and may be a primary or secondary disease. Pediatric primary CNS vasculitis is categorized differently than adult disease, with three pediatric categories of disease that are based on angiography and the distribution of involvement: (1) angiographic-positive nonprogressive disease, (2) angiographic-positive progressive disease, and (3) angiographic-negative disease.[322,369-374]

### Definition and Classification

Primary CNS vasculitis is diagnosed based on the initial criteria of Calabrese, including newly acquired focal or diffuse neurologic deficit, angiographic and/or histologic evidence of CNS vasculitis, and exclusion of other systemic disease (systemic vasculitis, infection, oncologic disease), with the additional pediatric criteria of new-onset psychiatric manifestations in patients 18 years and younger.[373,375,376]

### Epidemiology

The incidence of primary CNS vasculitis is unknown because this condition and its various phenotypes continue to be recognized.

### Clinical Features

New-onset neurologic and psychiatric manifestations can range from an acute stroke to isolated psychosis. Angiographic-positive disease typically is seen with headache and focal deficits, such as acute hemiparesis, motor and sensory deficits, loss of speech, and seizures. Children with progressive angiographic-positive disease and angiographic-negative disease are more likely to be seen with more diffuse deficits, including headaches, seizures, memory impairment, and psychiatric features such as psychosis and personality and behavior changes. The initial neurologic deficits may be mild or intermittent, but with time tend to become more prominent and disabling.[372,376,377]

Angiographic-negative disease is associated with more systemic signs of inflammation, including fever and malaise along with neurocognitive decline, behavioral changes, and often intractable seizures. Patients can also have focal deficits, optic neuritis, and myelitis. Disease can progress rapidly during days or be more insidious, with progression of neurologic and/or psychological manifestations during weeks to months.[370,372,376,377]

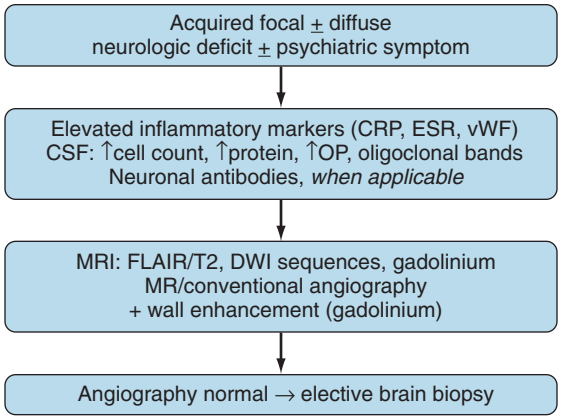

**Figure 108-16** Proposed diagnostic algorithm for children with suspected central nervous system vasculitis. CRP, C-reactive protein; CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; ESR, erythrocyte sedimentation rate; FLAIR, fluid-attenuated inversion recovery; OP, opening pressure; vWF, von Willebrand factor.

### Diagnosis and Diagnostic Tests

Recommendations for evaluating children with possible CNS vasculitis have been proposed (Figure 108-16). Imaging should be obtained in all children presenting with signs and symptoms concerning for an inflammatory brain disease. MRI with and without gadolinium may identify areas of ischemia, diffusion-restricted lesions, parenchymal lesions, and leptomeningeal disease.[378-381] Magnetic resonance angiography and angiography may reveal classic signs of vasculitis, such as stenosis, beading, and collateralization, with conventional angiography considered the gold standard.[382]

Extensive laboratory studies should be performed to both confirm the diagnosis of CNS vasculitis and to rule out other systemic diseases, such as systemic vasculitis, infections, metabolic, oncologic, and other neurologic conditions. Children with angiographic-negative disease and progressive angiographic-positive CNS vasculitis commonly have elevated inflammatory markers, whereas those with nonprogressive disease usually have normal studies. von Willebrand factor antigen may be a marker of disease and correlates with disease activity in some patients. CSF studies may reveal mild pleocytosis, elevated protein, oligoclonal bands, and elevated opening pressure.[322,369,370,372,374,376,377,380,383-385] However, patients with all forms of CNS vasculitis can also have normal or near-normal markers of inflammation despite extensive disease.

Brain biopsy is required to confirm a diagnosis of angiographic-negative CNS vasculitis but is not required in children with angiographic disease in the right clinical setting. Lesional biopsies are preferred when possible, but given the diffuse nature of angiographic-negative disease, nonlesional biopsies in the nondominant hemisphere are also acceptable. The yield of brain biopsies in pediatrics is 90%, with nondiagnostic biopsies most commonly the result of inadequate samples.[369,371,386]

### Treatment

The treatment of primary CNS vasculitis varies based on the disease subtype. There are no randomized controlled

trials for pediatric primary CNS vasculitis, but a prospective cohort study showed the efficacy and safety of a 6-month course of cyclophosphamide and high-dose steroids, followed by maintenance therapy with MMF or azathioprine for angiographic-negative disease.[387,388] Similar therapy is considered in those with progressive angiographic-positive disease. Nonprogressive disease may be successfully managed with CSs and anti-coagulation.[369,370,380,389]

### Outcome

There are limited data regarding long-term outcomes. Although two-thirds of children with nonprogressive angiographic-positive disease have a monophasic course, because they often are seen with strokes, they also have higher residual deficits. Progressive disease and angiographic-negative disease have more diffuse inflammation and reversible deficits when identified early and treated aggressively, allowing the majority of children to have good outcomes. Disease flares are common, and the long-term outcome of children with CNS vasculitis is not known.[369,370,380,389]

PART 17 INFECTION AND ARTHRITIS

CHAPTER 109

# Bacterial Arthritis

Paul P. Cook • Dawd S. Siraj

## KEY POINTS

- Acute bacterial arthritis is a medical emergency that warrants rapid, accurate diagnosis and immediate treatment along with appropriate consultation with specialists as needed.
- Most cases of native joint infection are the result of bacteremic seeding.
- *Staphylococcus aureus* is the most frequent microorganism in adult nongonococcal septic arthritis.
- The initial selection of an antibiotic regimen should be broad enough to take into account host factors, clinical characteristics, likely causative microorganisms, and regional antibiotic sensitivity data pending confirmation of bacteria by culture and sensitivities.
- An infected joint must be adequately drained, and an antibiotic course that is sufficiently long to cure the infection must be instituted. Surgical drainage should be considered, but only if needle aspirations are unsuccessful or impractical.
- Poor prognostic factors in bacterial joint infection include old age, underlying rheumatoid arthritis, and infection in a prosthetic joint.
- Débridement, antibiotics, and implant retention (DAIR) is a reasonable option for selected patients with early prosthetic joint infections.
- Late prosthetic joint infections require antibiotic treatment directed at the isolated microorganism and the complete removal of the infected prosthesis before reimplantation of a new prosthesis in a one-stage or two-stage operation.
- Reducing the risk of a prosthetic joint infection involves a thorough pre-operative evaluation, peri-operative use of antibiotics, and the careful use of antibiotic prophylaxis when a patient with a prosthesis is exposed to transient bacteremia. Clinical evidence does not support the use of antibiotic prophylaxis for most dental procedures.

## EPIDEMIOLOGY

Bacterial infections of the joint are usually curable with treatment, but morbidity and mortality are still significant in patients with underlying rheumatoid arthritis (RA), patients with prosthetic joints, elderly patients, and patients who have severe and multiple comorbidities. Incremental knowledge of the pathogenesis of septic arthritis caused by two common organisms, *Neisseria gonorrhoeae* and *Staphylococcus aureus*, and understanding of the pathobiology of prosthetic devices may lead to innovations in the management and prevention of bacterial joint infections.

The normal diarthrodial joint is resistant to bacterial infection because of local and systemic host defenses. Bacteria can reach the synovial-lined joint, however, via the hematogenous route and result in septic arthritis. The large joints are affected more commonly than the small joints, and monoarticular infection is the rule, with polyarticular infection (more than one joint involved) in less than 20% of cases. A prospective series from a community-based population in the Netherlands reflected a representative distribution of joint involvement: knee, 55%; ankle, 10%; wrist, 9%; shoulder, 7%; hip, 5%; elbow, 5%; sternoclavicular joint, 5%; sacroiliac joint, 2%; and foot joint, 2%.[1]

The incidence of septic arthritis ranges from 4 to 10/100,000/year in the general population, 5.5 to 12/100,000/year in children, 28 to 38/100,000/year in patients with RA, and 40 to 68/100,000/year in patients with joint prostheses.[2,3] The incidence appears to be increasing, probably related to orthopedic procedures, an aging population, and the increased use of immunosuppressive therapy.[4] The organisms causing bacterial arthritis depend on the epidemiologic circumstances (Table 109-1). Monoarthritis of a prosthetic joint in an elderly man is likely the result of *Staphylococcus*, whereas a migratory arthritis in a sexually active woman with skin lesions is likely caused by disseminated gonococcal infection. Septic arthritis caused by methicillin-resistant *S. aureus* (MRSA) is common in the elderly, in people who use intravenous drugs, and in individuals with prosthetic joints.[5]

## ETIOLOGY

The three main etiologies to consider when a patient is seen with acute monarticular arthritis are trauma, infection, and crystal-induced synovitis such as gout or pseudogout. Acute bacterial arthritis is most commonly monarticular. Most cases of septic arthritis result from hematogenous seeding of the synovial membrane. The abundant vascular supply of the synovium and the lack of a limiting basement membrane allow organisms to target joints during bacteremia. Less common causes of septic arthritis include direct inoculation after joint aspiration or corticosteroid injection of a joint; animal or human bites; nail puncture wounds or plant

thorn injury; joint surgery, especially hip and knee arthroplasties; and spread by contiguous osteomyelitis, cellulitis, or septic bursitis.

Table 109-1 lists the common organisms that cause joint infections according to the age of the patient and whether the joint is native or prosthetic.[4] Overall, *S. aureus* is the most common etiologic agent among children of all age groups, followed by group A streptococci and *Streptococcus pneumoniae*.[6,7] Neonates and infants younger than 2 months old are more susceptible to group B streptococci and Gram-negative enteric bacilli than older children. Rarely, *Pseudomonas*, *N. gonorrhoeae*, and *Candida albicans* may be responsible in very young children. Since the introduction of the *Haemophilus influenzae* type B vaccine, the incidence of septic arthritis caused by *H. influenzae* has declined dramatically.[8] In sexually active adolescents, *N. gonorrhoeae* must be considered. *Pseudomonas aeruginosa* and *Candida* are potential pathogens in adolescent intravenous drug abusers. Patients with sickle cell anemia are prone to *Salmonella* arthritis, and immunocompromised children are at higher risk for infection with Gram-negative bacilli. Other unusual joint pathogens in children include *N. meningitidis*, anaerobes, *Brucella*, and *Kingella kingae*.

The organisms causing nongonococcal septic arthritis in adults are 75% to 80% Gram-positive cocci and 15% to 20% Gram-negative bacilli.[9] *S. aureus* is the most common organism in native and prosthetic joint infections. *Staphylococcus epidermidis* is common in prosthetic joint infections but is a rare cause of native joint infections. *Staphylococcus lugdunensis* is a unique coagulase-negative *Staphylococcus* that can cause infection in prosthetic and native joints (particularly following arthroscopy). Unlike other coagulase-negative staphylococci, *S. lugdunensis* frequently causes severe systemic infections similar to what is seen with *S. aureus* infection. The streptococci, including *S. pneumoniae*, are the next most common group of Gram-positive aerobes. *Streptococcus pyogenes* is followed by groups B, G, C, and F in frequency. Patients with non–group A streptococcal disease often have comorbidities such as immunosuppression, diabetes mellitus, malignancy, and severe genitourinary or gastrointestinal infections.[10] Group B streptococcal arthritis in adults is uncommon, but it can be a serious infection in adult diabetics and patients with late prosthetic hip infections.[11] Aggressive polyarthritis caused by group B streptococci may result in serious functional damage and permanent morbidity. Patients predisposed to Gram-negative bacillary infections include patients with a history of intravenous drug abuse, very young and very old patients, and immunocompromised patients.[12] The most common Gram-negative organisms are *Escherichia coli* and *P. aeruginosa*.

Anaerobes account for 5% to 7% of septic arthritis.[1,2,13] Common anaerobes include *Bacteroides* sp., *Propionibacterium acnes*, and various anaerobic Gram-positive cocci. Predisposing factors include wound infections, joint arthroplasty, and immunocompromised hosts. Foul-smelling synovial fluid or air in the joint space should raise the suspicion of anaerobic infection, and appropriate cultures should be

obtained and held for at least 2 weeks. Anaerobes and coagulase-negative staphylococci are more common in prosthetic joint infections.

Polyarticular (two or more joints) septic arthritis is much less common than monoarticular infection.[14] Polyarticular septic arthritis is usually seen in patients with systemic inflammatory disorders, such as the spondyloarthropathies, RA, systemic lupus erythematosus, and other connective tissue diseases or in patients with overwhelming sepsis.[14,15] Approximately one-fourth of septic arthritis in patients with RA are polyarticular.[16] Intravenous drug abusers have also a high prevalence of polyarticular septic arthritis. Although *S. aureus* is the most common pathogen, group G streptococci, *H. influenzae*, *S. pneumoniae*, or mixed aerobic and anaerobic bacteria have been responsible for polyarticular infections. Involvement of more than one joint also can occur in certain patient populations such as neonates and patients with sickle cell anemia, or with certain organisms, such as *N. gonorrhoeae*, *N. meningitidis*, and *Salmonella*.[17]

Polymicrobial (two or more bacterial species), polyarticular septic arthritis is a rare clinical entity.[18] Large joints are usually affected. Among five reported cases, the knee was affected in four cases (bilaterally in two); the elbow and wrist were affected in three cases, and the shoulder was affected in two cases. The mean number of joints infected was three. Bacteremia was present in all but one case (80%) and always involved the same organisms that were in the synovial fluids. Most bacterial species isolated were the usual organisms seen in septic arthritis. Combinations of Gram-positive aerobic and anaerobic organisms were common. A characteristic of most cases (80%) was the extension of locally destructive processes as a result of the contiguous spread of infection from the affected joints, such as osteomyelitis, fasciitis with compartment syndrome, and abscess or sinus tract formation. Systemic complications, including septic shock, multiorgan failure, and toxic shock syndrome, were noted in 60% of cases. The mortality rate of polymicrobial, polyarticular septic arthritis in this small series was 60%.[18]

Arthrocentesis is a common procedure frequently used in conjunction with corticosteroid administration in patients with various forms of joint diseases. Septic arthritis after joint aspiration and injection is extremely rare, occurring in 4 cases per 10,000 injections.[3] Arthroscopic surgery is also a common procedure that is complicated by a low incidence of septic arthritis (<0.5% of procedures).[19] Coagulase-positive and coagulase-negative staphylococci account for more than 87% of these infections. In rare cases of septic arthritis of the knee related to anterior cruciate ligament repair, the tissue allografts were identified as the source of the infection.[20] Cultures yielded Gram-negative organisms such as *Pseudomonas aeruginosa*, *Citrobacter*, *Klebsiella oxytoca*, and mixed infection with *S. aureus*, *Enterococcus faecalis*, and *P. aeruginosa*.

## PATHOGENESIS

Acute bacterial arthritis is usually designated gonococcal or nongonococcal. In the case of gonococcal arthritis, *N. gonorrhoeae* possesses a variety of virulence factors on the cell surface. *N. gonorrhoeae* is able to attach to cell surfaces via filamentous outer-membrane appendages, or pili. Another outer membrane protein, protein I, has forms IA and IB. Protein IA binds the host factor H and inactivates complement component C3b, circumventing the host's complement system.[21] Protein IA also prevents phagolysomal fusion in neutrophils, enabling survival of the organism within the phagocytes. Lipo-oligosaccharide is a gonococcal molecule similar to lipopolysaccharide of other Gram-negative bacteria and possesses endotoxin activity, which contributes to the joint damage seen in gonococcal arthritis.[22]

**TABLE 109-2** Virulence Factors of *Staphylococcus aureus* and Their Mechanisms of Action

| Virulence Factor | Mechanism of Action |
|---|---|
| Collagen-binding protein | Binds collagen |
| Clumping factor A and B | Binds fibrinogen |
| Fibronectin-binding protein A and B | Binds fibronectin |
| Capsular polysaccharide | Anti-phagocytic |
| Protein A | Binds fragment crystallizable portion of IgG |
| Toxic shock syndrome toxin-1 | Superantigen |
| Enterotoxins | Superantigens |

*S. aureus* is the most common organism that causes nongonococcal arthritis. The virulence of *S. aureus* is associated with its ability to attach to host tissue within the joint, evade host defenses, and cause damage to the joint. Table 109-2 lists some of these virulence factors and their mechanisms of action. The attachment of *S. aureus* to the joint tissues is facilitated by microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). MSCRAMMs are embedded in the cell wall peptidoglycan of *S. aureus* (Figure 109-1).[23] They bind to host matrix proteins, including collagen, fibrinogen, elastin, vitronectin, laminin, and fibronectin. Gene knockout experiments in animal models showed that the gene coding for the protein that binds collagen is an important virulence factor for *S. aureus* joint infections.[24] Most *S. aureus* isolates also express the fibronectin-binding proteins, FnbpA and FnbpB. Disruption of the respective genes, *fnbpA* and *fnbpB*, by knockout gene experiments completely obliterates adherence of *S. aureus* to fibronectin-coated surfaces (e.g., prosthetic joints).[25]

The genes of several *S. aureus* cell surface proteins (e.g., protein A, fibronectin-binding proteins, coagulase) and exotoxins (e.g., toxic shock syndrome toxin [TSST]-1, enterotoxin B, proteases, and hemolysins) are regulated by the accessory gene regulator *agr*.[26] At low cell numbers, such as at the time of infection, production of cell surface proteins for attachment to host tissues is facilitated by the *agr* gene. When the cells have attached to tissue or an orthopedic device and have passed from the exponential to stationary phase of growth, *agr* represses the expression of genes coding for cell surface proteins and activates genes coding for exotoxins and tissue-destroying exoenzymes. Because of this complex effect on the different stages of infection, inhibitors of *agr* may reduce tissue destruction but enhance tissue colonization. This effect could have implications for chronic infections such as occur with prosthetic joints.

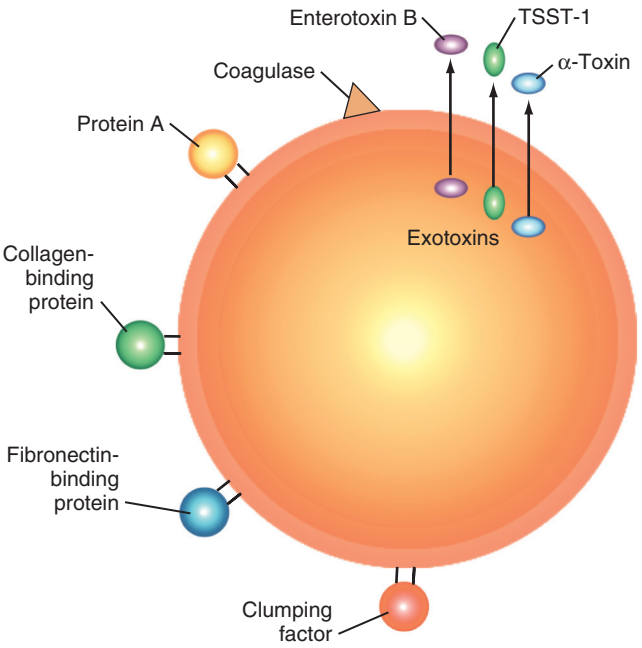

**Figure 109-1** Schematic diagram of *Staphylococcus aureus*. Many of the cell surface proteins are regulated by the agr locus (see text in Pathogenesis section). At low cell concentrations, agr facilitates the production of the cell surface proteins, which facilitate attachment to tissue. At higher cell concentrations, as occurs with establishment of infection, agr downregulates production of the cell surface proteins and activates genes coding for exotoxins. TSST, Toxic shock syndrome toxin.

Adherence receptors may allow intra-cellular movement of *S. aureus* into host cells (e.g., osteoblasts, endothelial cells, neutrophils).[27] The ability of *S. aureus* to switch from a normal colony phenotype to a slow-growing, antibiotic-resistant, small-colony variant phenotype may partially explain why this organism causes persistent and recurrent infections.[28] When internalized, the organism is protected from the host's immune system and from anti-microbial agents. After adherence to the joint tissue, the bacteria activate the host immune response. Opsonization and phagocytosis are key defenses to eradicate the organism. *S. aureus* possesses two virulence factors, protein A and capsular polysaccharide, which interfere with these defenses. Protein A interferes with binding of complement by binding to the fragment crystallizable (Fc) portion of immunoglobulin (Ig)G. Protein A has been termed a *superantigen* for B cells because 30% of human B cells show Fab-mediated binding of the protein A molecule.[29] Binding of protein A by B cells leads to activation and, subsequently, to depletion of B cells through apoptosis.[30] This process may have implications regarding the ability of the immune system to control infection with *S. aureus*. The gene coding for protein A had been experimentally disrupted, and joint infection caused by the altered strain in a mouse model resulted in less joint destruction than infection caused by the wild-type strain.[31]

Capsular polysaccharide interferes with opsonization and phagocytosis. Of the 11 reported capsule serotypes of *S. aureus*, types 5 and 8 account for 85% of clinical infections.[32] The capsule of these two serotypes is thinner, which facilitates the attachment to host fibronectin and fibrin.[33] When attached to these host proteins, capsule production is upregulated to form a thicker capsule, which makes the bacteria more resistant to opsonization and phagocytosis. The thicker capsule can also conceal the highly immunogenic adherence proteins (MSCRAMMs).[34] A mutant of the type 5 capsule in a murine model had a lower rate of infection and resulted in less severe arthritis compared with mice infected with the wild-type strain.[35] A vaccine consisting of types 5 and 8 polysaccharide reduced *S. aureus* bacteremia by more than half in hemodialysis patients.[36] The duration of protection was approximately 40 weeks after a single vaccination.

*S. aureus* exotoxins (e.g., TSST-1 and enterotoxins) act as superantigens that bind to host class II major histocompatibility complex (MHC) molecules and T cell receptors, resulting in clonal expansion and activation of some T cells. This activation triggers the release of numerous cytokines, including IL-2, interferon (IFN)-γ, and TNF.[37] Induction of these cytokines results in systemic toxicity and joint damage. The stimulated T cells initially proliferate but later disappear, likely because of apoptosis, and result in immunosuppression.[38] Internalized organisms that had been protected from this inflammatory response may cause fulminant or persistent infection. Mice injected with strains of *S. aureus* lacking TSST-1 and enterotoxins rarely develop arthritis; when arthritis is induced, it is much milder compared with arthritis in animals injected with the wild-type strain.[37] Vaccination of mice with a mutated, recombinant form of enterotoxin A devoid of superantigen function was associated with a significant reduction in mortality.[39]

In response to bacterial infection of the joint space, the host releases a variety of cytokines and inflammatory mediators. Initially, IL-1β and IL-6 are released into the joint space, leading to an influx of inflammatory cells. These neutrophils and macrophages engulf invading bacteria and release additional cytokines, including TNF, IL-1, IL-6, and IL-8. Blocking TNF with a monoclonal antibody and IL-1 with an IL-1 receptor antagonist inhibited leukocyte infiltration into the joint by 80% in a rabbit model of *S. aureus*–induced arthritis when the cytokine inhibitors were given simultaneously with *S. aureus*.[40] When the same inhibitors were given 24 hours after infection, however, there was no effect on leukocyte infiltration, suggesting the crucial roles of TNF and IL-1 in the early stages of *S. aureus*–induced arthritis. Release of IFN-γ is associated with the influx of T cells, which occurs a few days after infection. In a mouse model of *S. aureus* septic arthritis, IFN-γ has been associated with a worsening of the severity of arthritis while protecting the animals from septicemia.[41] The host's early cytokine response may aid the clearance of organisms and limit infection in the host. A late cytokine response may amplify the destructiveness of an established infection.

## CLINICAL FEATURES

The classic presentation of nongonococcal septic arthritis is the acute onset of pain, swelling, and decreased range of motion in the affected joint. Large joints are affected most commonly. In adults, the knee is involved in more than 50% of cases; hip, ankle, and shoulder infections are less common.[41] In infants and small children, the hip is more often involved.[42] Patients with septic arthritis often have underlying illnesses and predispositions to infections. Many

are immunocompromised, are intravenous drug abusers, have prosthetic joints, and have diseases such as neoplasia, renal failure, and RA. Table 109-3 lists the risk factors that predispose to septic arthritis.[2,4,43]

Most patients with bacterial arthritis are febrile, although chills are unusual. Fever may be absent in elderly patients. In children, septic arthritis usually is accompanied by fever, malaise, poor appetite, irritability, and progressive reluctance to use the affected limb. Physical examination typically reveals warmth and tenderness of the affected joint, joint effusion, and limited active and passive range of motion. Septic arthritis among patients with RA has been a special challenge to clinicians because in many cases, it is difficult to differentiate septic arthritis in a joint already affected by RA from rheumatoid flare. Septic arthritis in patients with RA is associated with poor joint outcome and high mortality.[44] Whenever bacterial arthritis is suspected, the most important diagnostic procedure is arthrocentesis and examination of the synovial fluid. For joints that are deep and more difficult to aspirate, ultrasound-guided or fluoroscopy-guided needle aspiration should be done.

Disseminated gonococcal infection (DGI) occurs in 1% to 3% of patients infected with *N. gonorrhoeae*. DGI is three times more common in women than men. Women are more commonly affected because they are more likely to have asymptomatic and untreated primary infections. Bacterial dissemination has been associated with intrauterine devices and has occurred during menstruation, pregnancy, and pelvic operation.[45] Gonococcal arthritis develops in approximately 42% to 85% of patients with DGI.[46]

Gonococcal arthritis is the most common cause of acute monarthritis in sexually active young adults. In the 1970s it accounted for almost two-thirds of all septic arthritis and tenosynovitis cases in North America. Clearance of gonococcal infection is dependent on a potent complement-mediated immune response. Individuals with terminal complement (C5-8) deficiency are at greater risk for infection.[47]

Patients with gonococcal joint disease typically are seen with one of two forms. The first form is seen in patients with DGI and is characterized by fever, shaking chills, vesiculopustular skin lesions, tenosynovitis, and polyarthralgias. Blood cultures are frequently positive, whereas synovial fluid cultures are rarely positive. *N. gonorrhoeae* can be cultured from genital, rectal, and pharyngeal sites. Tenosynovitis of multiple tendons of the wrist, fingers, ankle, and toes is a unique feature of this form of DGI and distinguishes it from other forms of infectious arthritis. In the second form, patients have localized joint infection without the systemic manifestations classic to DGI. Clinical findings are similar to those seen in nongonococcal septic arthritis. Patients have purulent arthritis, most commonly of the knee, wrist, or ankle, and more than one joint can be infected simultaneously. *N. gonorrhoeae* frequently can be cultured from the synovial fluid.[46]

## DIAGNOSIS AND DIAGNOSTIC TESTS

Whenever bacterial arthritis is suspected, the most important diagnostic procedures are arthrocentesis and examination of the synovial fluid. Arthrocentesis and synovial fluid analysis should be performed in patients who are seen with an inflamed joint for which alternative explanations are not immediately apparent. For example, a patient with a history of gout or evidence of a generalized flare of rheumatoid arthritis might not require arthrocentesis. However, the clinician should follow up carefully and reassess for an infectious process if the decision is made to treat for a diagnosis other than infection. For joints that are deep and more difficult to aspirate, ultrasound-guided or fluoroscopy-guided needle aspiration should be done.

Normal joints contain a small amount of synovial fluid that is clear, is highly viscous, and has few white blood cells (WBCs). The protein concentration is approximately one-third that of plasma, and the glucose concentration is similar to that of plasma. Infected synovial fluid is usually purulent with an elevated leukocyte count typically greater than 50,000 WBC/mm$^3$ and often exceeding 100,000 WBC/mm$^3$ with polymorphonuclear cell predominance. Synovial fluid levels of glucose, lactate dehydrogenase, and total protein have limited value in the diagnosis of septic arthritis. Although a low synovial fluid glucose (<40 mg/dL or less than half the serum glucose concentration) and an elevated lactate dehydrogenase suggest bacterial infection, they are not sufficiently sensitive or specific for the diagnosis.[48] Figure 109-2 is an algorithm for synovial fluid analysis, and Table 109-4 lists the differential diagnoses of septic arthritis and the known causes of pseudoseptic arthritis.[49]

A definite diagnosis of bacterial arthritis can be made only by visualizing bacteria on a Gram-stained smear or by culturing bacteria from the synovial fluid. In patients not previously treated with antibiotics, synovial fluid cultures are positive in 70% to 90% of cases of nongonococcal bacterial arthritis.[4,50] Blood cultures are positive in 40% to 50% of cases of septic arthritis and are the only method of

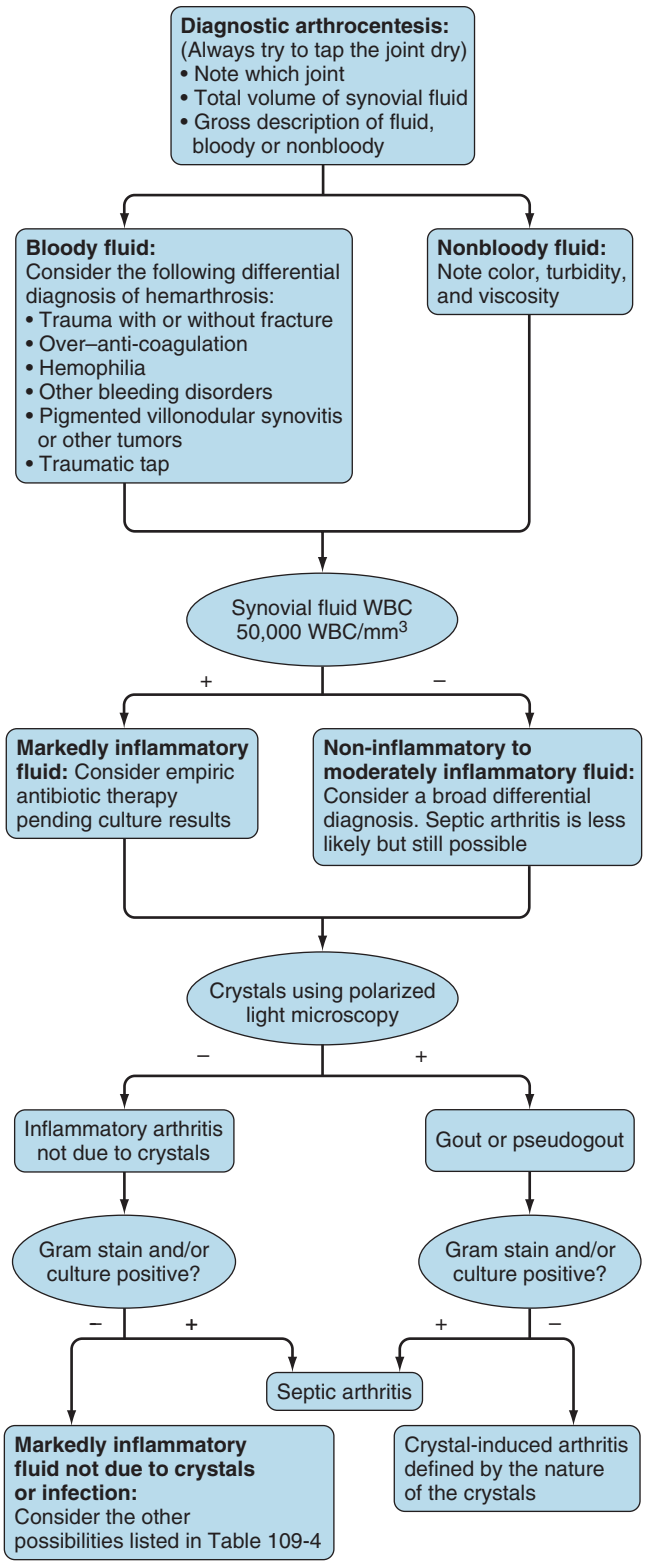

**Figure 109-2** Algorithm for synovial fluid analysis in septic arthritis. WBC, white blood cells.

*Extremely inflammatory synovitis with negative culture is referred to as *pseudoseptic arthritis.* Typically, synovial fluid analysis shows ≥50,000 white blood cells (WBC)/mm$^3$. Often the WBC count is >100,000 WBC/mm$^3$.

Data from Dubost JJ, Soubrier M, De Champs C, et al: No changes in the distribution of organisms responsible for septic arthritis over a 20 year period. *Ann Rheum Dis* 61:267–269, 2002; Weston VC, Jones AC, Bradbury N, et al: Clinical features and outcome of septic arthritis in a single UK health district 1982–1991. *Ann Rheum Dis* 58:214–219, 1999; and Coakley G, Mathews C, Field M, et al; British Society for Rheumatology Standards, Guidelines and Audit Working Group: BSR & BHPR, BOA, RCGP and BSAC guidelines for management of the hot swollen joint in adults. *Rheumatology (Oxford)* 45:1039–1041, 2006.

identifying the pathogen in approximately 10% of cases.[51,52] Occasionally, an extra-articular site of infection offers a clue to the etiologic organism infecting the joint. Examples include septic arthritis in association with pneumococcal pneumonia, *E. coli* urinary tract infection, and cellulitis caused by staphylococci or streptococci. Gram-positive cocci are identified in 50% to 75% of synovial fluid Gram-stained smears, but Gram-negative bacilli are identified less than 50% of the time in culture-proven cases.[50]

Inflammatory markers such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and WBC are usually raised, but the sensitivity is low, and their absence does not exclude the diagnosis of septic arthritis.[43,53] Procalcitonin, the peptide precursor of calcitonin, has been extensively investigated as a biomarker for bacterial infection.[54] Procalcitonin levels are elevated in bacterial infections, and the levels return to normal relatively rapidly once the bacterial infection is controlled. Unlike the ESR and CRP, procalcitonin levels are not elevated in many other inflammatory conditions, such as gout, systemic lupus erythematosus, or Still's disease.[55] Also, the levels are not affected by NSAIDs or glucocorticoids. It is postulated that cytokines and endotoxins released from bacteria inhibit conversion of procalcitonin to calcitonin. Viral infections are not associated

with procalcitonin elevations because viruses stimulate release of IFN, which blocks procalcitonin production in human cells. The majority of procalcitonin is produced in nonthyroidal tissue. Therefore procalcitonin elevations may occur in post-thyroidectomy patients who have a bacterial infection. In healthy individuals, serum procalcitonin levels are less than 1 ng/mL. A meta-analysis of studies on the use of procalcitonin for the diagnosis of septic arthritis recommended that procalcitonin be used as a rule-in test at the cutoff value of 0.5 ng/mL and as a rule-out test at the cutoff value of 0.3 ng/mL, with specificity and sensitivity in the range of 90%.[56] In this meta-analysis, procalcitonin was more sensitive and specific than CRP for diagnosing or ruling out septic arthritis.

Culture for *N. gonorrhoeae* is almost always negative in skin lesions and is positive in less than 50% of synovial fluid samples and in less than one-third of blood cultures; this phenomenon may be the result of the fastidious growth requirements of *N. gonorrhoeae*. The organism can often be easily recovered from other sites, such as urethral, cervical, rectal, or pharyngeal specimens (i.e., the genitourinary tract). In culture-negative septic arthritis in which *N. gonorrhoeae* is suspected, polymerase chain reaction techniques can be used to detect gonococcal DNA in the synovial fluid. Unfortunately, the technique is not standardized and is not widely avilable.[57]

When culturing the synovial fluid, it should be brought directly to the laboratory and placed on conventional broth and solid media or into aerobic and anaerobic blood culture bottles. Inoculating blood culture bottles with 5 to 10 mL of joint fluid or smaller volumes into isolator tubes may increase the yield of positive cultures beyond that of standard techniques.[58,59] Synovial fluid culture can use specialized collection and detection systems that can identify significantly more pathogens and fewer contaminants than culture by the agar-plate method.[60]

Plain radiographs in septic arthritis are usually normal early in the course of the infection, but baseline films should be obtained to look for evidence of other disease and contiguous osteomyelitis. Radiographs often show nonspecific changes of inflammatory arthritis, including periarticular osteopenia, joint effusion, soft tissue swelling, and joint space loss. In more advanced infection, periosteal reaction, marginal or central erosions, and destruction of subchondral bone may be seen. Bony ankylosis is a late sequela of septic arthritis. Dislocation or subluxation of the femoral head is unique to hip infection of neonates.[61]

Ultrasound of the hip is the modality of choice to detect fluid collections in this deep joint and can serve as a guide in its aspiration. Ultrasound can be similarly used in other joints, such as the popliteal cyst of the knee, shoulder, acromioclavicular, or sternoclavicular joints. Triple-phase bone scan using technetium 99m is often done in children to identify an associated metaphyseal osteomyelitis or avascular necrosis of the femoral head. Whole-body bone scan is preferred in young children because, despite focal symptoms, septic arthritis and osteomyelitis may be multifocal in this age group.[62] In septic arthritis of all age groups, the periarticular distribution of increased uptake is seen on the early "blood-pool" phase and the delayed images of the joint. Bone scans provide only nonspecific information, however, and cannot differentiate septic from noninfectious causes of joint inflammation. Bone scans are more sensitive than standard radiography in the diagnosis of arthritis because radionuclide uptake precedes morphologic bone changes that are seen on radiograph. A suggestive bone scan must be interpreted in the proper clinical context and supported by microbiologic data for a definitive diagnosis of joint or bone infection.

In joints that are difficult to evaluate otherwise or that have complex anatomic structures, computed tomography (CT) and MRI can provide useful images to delineate the extent of the infection.[63] MRI is highly sensitive in early detection of joint fluid and is superior to CT in the delineation of soft tissue structures and soft tissue abscess. These images can show early bone erosion, reveal soft tissue extension, and facilitate arthrocentesis of joints such as shoulders, hips, acromioclavicular,[64] sternoclavicular, sacroiliac, and facet joints of the spine. MRI findings such as reactive bone marrow can suggest the presence of secondary osteomyelitis, which can complicate septic arthritis. When multiple joint involvement is suspected, triple-phase bone scintigraphy is the preferred modality of investigation.

## TREATMENT

Treatment of septic arthritis must begin immediately after the clinical evaluation is complete and all appropriate cultures are taken. A serious clinical suspicion of a joint infection warrants the initiation of empiric antibiotic therapy before culture confirmation is available. Delays in treatment allow the infection to become more established in the joint and permanently damage the articular cartilage. Untreated, there is the opportunity for the joint infection to spread to other body sites via the hematogenous route and become more widespread and more difficult to cure.

The principles of treatment of an infected joint, whether natural or prosthetic, follow those of treatment of an infected body cavity in which antibiotics must be used in conjunction with adequate drainage of the infected closed space. The clinical circumstances and the preliminary laboratory data aid the selection of antibiotic agents. Host factors, any extra-articular sites of infection, and the Gram-stained smear of the synovial fluid are the best early guides for the antibiotic agents with which to start. Table 109-5 lists current antibiotic agents for adults,[53] and Table 109-6 lists agents for children.[65]

Narrow antibiotic coverage is indicated if Gram-positive cocci are found in the synovial fluid, and the clinician suspects a primary source of staphylococcal infection from the skin. Appropriate monotherapy in this case may be a penicillinase-resistant penicillin or vancomycin if methicillin resistance is likely. If Gram-negative bacilli are noted in the synovial fluid, and the patient has a kidney infection, specific agents (e.g., ampicillin or a cephalosporin) against *E. coli* and other common urinary tract pathogens may be used. In healthy, young, sexually active individuals with community-acquired septic arthritis and a negative synovial fluid Gram-stained smear, ceftriaxone is a reasonable option to cover *N. gonorrhoeae*. If synovial fluid Gram stain shows Gram-positive cocci, vancomycin should be the empiric therapeutic option, considering the fact that a significant proportion of community-acquired *S. aureus* infections are now methicillin resistant.[66] A reasonable initial empiric

therapy to cover gonococci, *S. aureus*, and streptococci is ceftriaxone plus vancomycin, pending final culture results. In elderly debilitated patients or adults with low risk for sexually transmitted disease as well as a negative Gram-stained smear of synovial fluid, broad antibiotic coverage against a wide variety of organisms, including *S. aureus*, streptococci, and Gram-negative bacilli should be given initially. A typical regimen includes an anti-staphylococcal agent (e.g., vancomycin) plus a third-generation cephalosporin (e.g., ceftriaxone).

When the identity and the sensitivities of the organism are known, antibiotic therapy should continue with the most efficacious agent that has the best safety profile and narrowest spectrum. The parenteral route of antibiotic administration is the preferred initial treatment. Continued antibiotic therapy may be switched to oral agents if adequate blood levels can be achieved and maintained by this route. There is no evidence that the direct intra-articular instillation of drugs is necessary or preferable in septic arthritis because there is no barrier against the free diffusion of antibiotic agents from the blood to the synovial fluid. In cases in which uncertainty exists, serum and synovial fluid levels of antibiotic drugs can be measured to ensure that therapeutic levels are reached.

Most penicillins, cephalosporins (excluding ceftriaxone), and carbapenems (excluding ertapenem) have short half-lives necessitating frequent dosing (i.e., every 4 to 8 hours). Extended or continuous infusion therapy maintains levels of the drug above the minimal inhibitory concentration (MIC) for a longer period of time, thus improving clinical outcomes and providing for more convenience for patients and caregivers, particularly in the outpatient or home health setting. Selected extended and continuous infusion dosing is reflected in Figure 109-3. Use of once-daily drugs, such as ceftriaxone and ertapenem, is increasingly used in the outpatient management of septic arthritis. These drugs, because of high protein binding, may not be appropriate for morbidly obese patients.

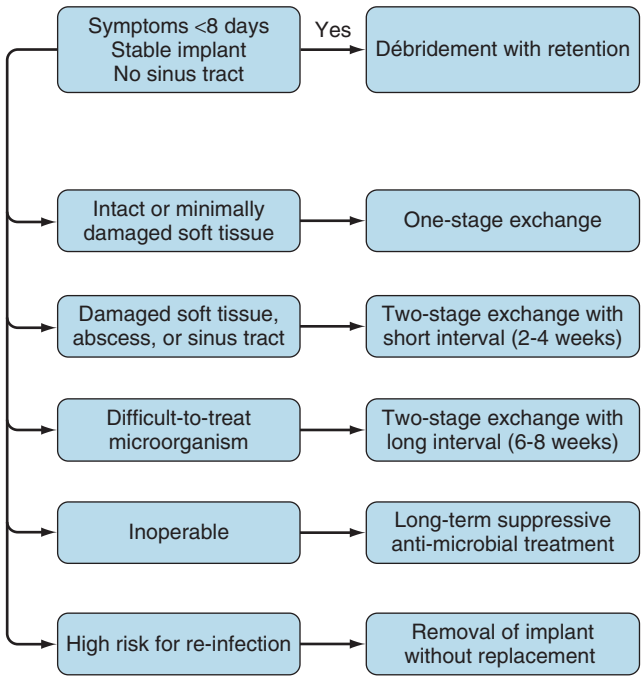

**Figure 109-3** Algorithm for the management of an infected joint prosthesis. *(Modified from Trampuz A, Zimmerli W: Prosthetic joint infections: update in diagnosis and treatment.* Swiss Med Wkly *135:243–251, 2005.)*

Most individuals with septic arthritis respond adequately to appropriate anti-microbial agents after initial joint aspiration for fluid analysis. In experimental infectious arthritis cases, early antibiotic therapy reduced the loss of collagen and erosion of articular surface, which minimizes the need for open surgical drainage.[67] It is generally accepted that prompt and adequate drainage of the septic joint is essential to decrease the risks of substantial loss of articular function; however, the best approach to drain the joint remains controversial.[68]

From retrospective studies, daily aspiration of an infected joint showed better functional outcome than open surgical drainage, although the former had higher overall mortality.[69,70] An explanation for higher mortality could be the higher comorbid conditions of patients who had daily aspirations than the ones who were more fit and underwent open surgical drainage.[69] If the synovial fluid cell count and polymorphonuclear percentage decrease with successive aspiration, the anti-microbial therapy is probably effective.[13,71] If needle aspiration is technically difficult (as in the hip or the shoulder) or does not provide thorough drainage of the joint, if the joint effusion does not resolve promptly, if sterilization of the joint fluid is delayed, if the infected joint is already damaged by pre-existing rheumatoid disease, or if infected synovial tissue or bone needs débridement, surgical drainage should be considered sooner rather than later.[13,50,72] Arthroscopy is emerging as an alternative to arthrotomy with the advantage of reduced surgical morbidity. Wound healing is faster, and rehabilitation time is shortened.[73] A retrospective analysis from the United Kingdom suggested that most patients can be treated medically (with repeated aspirations) and do not require surgical drainage (either by arthroscopy or arthrotomy).[74] Although statistically not significant, medical therapy resulted in more complete cure and less deterioration of functional status at time of discharge. Another study, which included 20 adults with native hip joint septic arthritis, concluded that symptom duration, especially if it is longer than 3 weeks before presentation, was a statistically significant predictor of the need for excision arthroplasty.[75] These results highlight the need for careful case selection for surgical intervention.

The optimal duration of antibiotic treatment has not been prospectively studied. For native joint infections caused by *N. gonorrhoeae*, a 1-week course of ceftriaxone should be adequate. For septic arthritis caused by organisms other than *N. gonorrhoeae*, therapy ranging from 2 weeks to 6 weeks is recommended depending on type, sensitivity of microorganism, and presence of osteomyelitis. If long-term antibiotics are chosen (4 to 6 week duration), parenteral antibiotics may be switched to oral antibiotics after 2 weeks, provided that there is clinical improvement, inflammatory markers are trending down, and oral antibiotics are available to which the microorganism is susceptible.[52] The duration of antibiotic administration can be 2 weeks for uncomplicated infection by susceptible microorganisms or 4 to 6 weeks for more extensive infection in an immunocompromised host. For septic arthritis caused by *H. influenzae*, streptococci, or Gram-negative cocci, 2 weeks of

antibiotic therapy is usually adequate. Staphylococcal septic arthritis usually requires 3 to 4 weeks of therapy, and for pneumococcal or Gram-negative bacillary infections, therapy should be continued for at least 4 weeks.[76,77]

During the first few days of management, immobilization of the infected joint by external splinting and adequate analgesic administration ensure patient comfort. Physical therapy, starting with passive then graduating to active motion, should be instituted as soon as the patient can tolerate mobilization of the inflamed joint because early active range-of-motion exercises are beneficial for ultimate functional recovery. Involving the orthopedic surgeon and the physical therapist early on in the course of treatment facilitates the best choice of drainage procedure and results in the best functional outcome.[78]

## PROSTHETIC JOINT INFECTIONS

Total joint replacement for advanced arthritis is one of the major advances in medicine in the 20th century and continues to improve in the 21st century. Infection of prosthetic joints is an uncommon but devastating complication of joint replacement surgery. More than 700,000 total knee arthroplasties (TKA) and 332,000 total hip arthroplasties (THA) were done in the United States in 2010.[79] Arthroplasties are increasing, and projections are that nearly 4 million arthroplasties (3.5 million TKA and 572,000 THA) will be done each year in the United States by 2030. In addition to hip and knee arthroplasties, shoulder, elbow, and ankle replacements are becoming more common, particularly in patients with RA. The infection rate of arthroplasties varies considerably among industrialized countries. Data from the United States indicate arthroplasty infection rates of 2% to 2.2%,[80] whereas European countries report infection rates of 0.8% and 1.2% for knees and hips, respectively.[81] In the United States, the infection rate is higher for elbow (3.3%) and lower for shoulder (1.3%) arthroplasties compared with hip and knee arthroplasties.[82,83] Infection rates are much higher in patients undergoing revision of a prosthetic joint compared with primary arthroplasty (3% for hips and 6% for knees).[84] The risk of infection is approximately twofold higher in patients with RA compared with patients with osteoarthritis.

The risk of prosthetic joint infection (PJI) is related to many factors. In a retrospective study of 56,216 total knee arthroplasties, the most important risks for infection included (1) a diagnosis of osteonecrosis (hazard ratio [HR], 3.65), (2) a diagnosis of post-traumatic arthritis (HR, 3.23), (3) male sex (HR, 1.89), (4) an American Society of Anesthesiologists (ASA) score of 3 or more (HR, 1.65), (5) body mass index of 35 or more (HR, 1.47), and (6) diabetes mellitus (HR, 1.28). Surgical risk factors included quadriceps-release exposure (HR, 4.76) and the use of antibiotic-laden cement (HR, 1.53).[85] Certain patient populations are at increased risk of infection because of comorbid conditions (e.g., diabetes mellitus and RA). Other risk factors include long operative time, use of disease-modifying anti-rheumatic drugs, and smoking.[85,86,87]

Orthopedic implants adversely affect host defenses. Prosthetic devices impair opsonic activity and diminish the ability of neutrophils to kill bacteria. Polymorphonuclear leukocytes release lysosomal enzymes and superoxide into the area surrounding the prosthesis, resulting in tissue damage and local devascularization. Phagocytes may be focused on removal of the foreign body such that fewer cells are available to fight infection. Finally, polymethylmethacrylate bone cement can inhibit neutrophil and complement functions, and the heat produced by the polymerization of polymethylmethacrylate can damage adjacent cortical bone and result in a devascularized necrotic area, which is ideal for bacterial growth. After implantation, prosthetic joints are immediately coated by host proteins, including albumin, fibrinogen, and fibronectin. *S. aureus*, which possesses numerous host protein-binding receptors (MSCRAMMs), is a common pathogen in infection of prosthetic joints. Patients with a prosthetic joint in whom *S. aureus* bacteremia develops have an approximate one in three chance of experiencing an infection of the implant.[88,89]

Another phenomenon crucial to development of infection is the ability of organisms to form biofilms on the surface of the prosthetic device. A biofilm is defined as "an assemblage of microbial cells that is irreversibly associated with a surface and enclosed in a matrix of primarily polysaccharide material."[90] Biofilm formation is a natural process. Organisms grow on indwelling medical devices, potable water system pipes, and living tissues. *S. epidermidis* is particularly adept at attaching to and forming biofilms on foreign bodies such as prosthetic joints. Small numbers of these organisms from the patient's skin or mucous membranes, or from the hands of the surgeons or clinical staff, contaminate and colonize the orthopedic device at the time of implantation. Staphylococcal surface proteins (SSP)-1 and SSP-2, are fimbria-like polymers that facilitate adherence of *S. epidermidis* to polystyrene. *S. epidermidis* produces a polysaccharide/adhesin substance crucial to the formation of this extra-cellular matrix known as *slime*. Polysaccharide/adhesin mutants are less virulent than the wild-type strain in a rabbit model of endocarditis.[91]

PJIs are divided into early onset (<3 months after placement), delayed (3 to 24 months post-surgery), and late onset (>24 months after placement). Early and delayed infections are usually related to surgical contamination at the time of the implantation, whereas late infections usually result from hematogenous seeding of the joint. Most infections occur within the first 2 years of implantation. Because of its high virulence, *S. aureus* accounts for most early and late infections (see Table 109-1). So-called *small-colony* variants of *S. aureus* may be responsible for persistent and recurrent infections of prosthetic implants.[92] These subspecies of *S. aureus* are difficult to treat because they grow slowly and are relatively resistant to cell-wall–active antimicrobial agents, anti-folate drugs (trimethoprim and sulfamethoxazole), and aminoglycosides. There is some concern that the practice of using gentamicin-impregnated polymethylmethacrylate beads to treat prosthetic joint infections may actually select for the small-colony variant species.[92] Delayed infections are usually caused by less virulent microorganisms such as coagulase-negative staphylococci and *P. acnes*. Because these low-virulence organisms are common skin contaminants, it is important to interpret culture results carefully.

Clinically, the most common symptom in patients with prosthetic joint infection is pain of the affected joint. Differentiating pain from mechanical loosening of the

prosthesis from pain related to infection can be difficult. Typically, a patient with mechanical loosening but no infection has pain only with motion, whereas a patient with infection experiences pain at rest and with motion. Warmth at the implant site, effusion, erythema, and fever are frequently associated with early and late, but not delayed, infections. This difference in clinical presentation likely represents the virulence of the most common organisms associated with the three categories of infection. The presence of a sinus tract with purulent discharge suggests involvement of the implant and is an indication for removal of the prosthesis. The Infectious Diseases Society of America (IDSA) has published guidelines regarding the diagnosis and management of patients with prosthetic joint infections.[93] Criteria for diagnosis of PJI are given in Table 109-7.

Inflammatory blood laboratory markers have variable sensitivity and specificity in the diagnosis of prosthetic joint infection. In a meta-analysis, elevated levels of IL-6 and CRP had a much higher sensitivity (97% and 88%, respectively) than an elevation of the WBC count or ESR (45% and 75%, respectively).[94] The specificity of an elevated level of IL-6 (91%) was the highest of these markers with elevation of WBC (87%), CRP (74%), and ESR (70%) somewhat lower. Inflammatory markers increase following arthroplasty, and the return to normal levels is quite variable. IL-6 will return to normal within a matter of a few days following surgery, whereas the CRP level may remain elevated for as long as 3 weeks and the ESR for several months following arthroplasy.[94] Therefore a low or normal CRP or IL-6 level in a patient with suspected prosthetic joint infection has a good negative-predictive value. Current IDSA guidelines recommend the use of CRP and ESR in the management of patients with proven or suspected PJI.[93] IL-6, TNF, and procalcitonin testing look promising but have not been incorporated into existing guidelines.[95] Because serum procalcitonin levels are easily obtainable from local hospitals or reference laboratories, it may be more practical to obtain procalcitonin levels. Serial plain radiographs may be helpful; the presence of subperiosteal bone growth and transcortical sinus tracts is specific for infection. Bone scans with technetium 99m–labeled methylene diphosphonate are sensitive but lack specificity because the bone scan is typically positive for 6 to 12 months after the original implantation. Bone scans may be a useful screening test for patients with suspected late prosthetic joint infection. CT has limitations because of the imaging artifacts caused by the metal implant. MRI can be performed only in patients with titanium or tantalum implants. IDSA guidelines do not recommend bone scans, leukocyte scans, MRI, CT scans, or positron-emission tomography for the routine management of PJI.[93]

Aspiration of the joint is essential in differentiating infection from noninfectious causes of joint pain, particularly in patients without RA.[93] In one study, a synovial fluid leukocyte count of greater than 1700/mm$^3$ had a sensitivity of 94% for determining infection, whereas a differential count of greater than 65% neutrophils had a sensitivity of 97%.[96] The specificities of these two measurements were 88% and 98%, respectively, in patients without underlying inflammatory diseases such as RA. Gram-stained smear of the synovial fluid has a low sensitivity (<20%) but a high specificity (>97%).[93] Cultures of drainage from a sinus tract are not helpful, unless the culture grows *S. aureus*.[97]

Generally, at least three tissue specimens should be taken at the time of surgery, including tissue from the joint capsule, synovial lining, bone-cement interface, and samples from purulent material or sequestrum.[93,98,99] Swabs of the joint have a low sensitivity and should be avoided. Unless the patient is septic or otherwise systemically ill, anti-microbial therapy should be discontinued a minimum of 2 weeks before the revision surgery, and peri-operative antibiotics should not be administered until all of the tissue cultures have been obtained.[93] Using this methodical approach, there is a direct correlation between the number of tissue specimens positive for a particular microorganism and the probability of infection. The probability of infection is estimated at less than 5% if all tissue specimens are negative and greater than 94% if three or more tissue specimens are positive for growth.[99] Finally, the location of the prosthesis is helpful in the interpretation of the positive culture. The isolation of *P. acnes* from a single tissue culture from a knee prosthesis is more likely to be a contaminant than if the same organism is obtained from a shoulder prosthesis.

For patients who have received recent antibiotics, there may be a role for sonication of the prosthesis at the time of explantation.[100] Culturing of the explanted prosthesis that has been sonicated to remove adherent bacteria had a higher sensitivity (75%) as compared with culture of periprosthetic tissue (45%) in patients who had received antibiotics in the past 14 days.[101]

Medical therapy of patients with prosthetic joint infections is challenging. Organisms existing in biofilms are much more resistant to anti-microbial agents for several reasons. Most anti-microbial agents penetrate the biofilm layer adequately but do not inhibit growth of bacteria within the biofilm matrix. Biofilm-associated organisms, including the small colony variants of *Staphylococcus aureus*, grow much slower (i.e., are in stationary-phase growth) than organisms in suspension. As a result, anti-microbial agents such as vancomycin, penicillins, and cephalosporins, which act on rapidly dividing organisms, are not effective in treating device-related infections.[102] Rifampin and fluoroquinolones (particularly moxifloxacin) may be more effective because they are active against organisms in the stationary phase of growth.[102] IDSA guidelines recommend rifampin in combination with another agent for the

**TABLE 109-7** Criteria for Diagnosis of Prosthetic Joint Infection (PJI)

| |
|---|
| The presence of a sinus tract that communicates with the prosthesis is definitive evidence of PJI (B-III). |
| The presence of acute inflammation on histopathologic examination of the periprosthetic tissue at the time of surgical débridement or prosthesis removal is highly suggestive evidence of PJI (B-II). |
| The presence of purulence without another known etiology surrounding the prosthesis is definitive evidence of PJI (B-III). |
| Two or more intra-operative cultures or combination of pre-operative aspiration and intra-operative cultures that yield the same organism may be considered definitive evidence of PJI. Growth of a virulent microorganism (e.g., *Staphylococcus aureus)* in a single specimen of a tissue biopsy or synovial fluid may also represent PJI (B-III). |

treatment of rifampin-susceptible strains of *S. aureus*.[93] There is evidence that clinical outcomes are improved in patients receiving rifampin, although the data are based on retrospective analysis.[103,104] The role of newer anti-staphylococcal antibiotics such as linezolid, daptomycin, telavancin, ceftaroline, dalbavancin, oritavancin, and tigecycline, is unclear at this time.[105] There is some evidence that oritavancin may be active against biofilm-associated small-colony variants of *Staphylococcus aureus*.[106]

Treatment of late prosthetic joint infections is complex. In most patients, effective therapy requires a combination of antibiotics with the removal of the orthopedic device. Failure to remove the infected prosthesis is frequently associated with an unacceptably high rate of relapse, probably related to biofilm formation on the orthopedic implant. Removal of the joint prosthesis, débridement of infected bone, and placement of a new prosthesis during the same operation has been associated with a high rate of recurrence of infection, but studies indicate that single-stage revision or débridement with retention of the prosthesis may be effective in certain situations.[107] Patients who have had symptoms of pain and swelling of the joint for less than 8 days[107] or less than 3 weeks[108] and who have a stable prosthesis with little soft tissue damage and no sinus tract are candidates for débridement, antibiotics, and implant retention (DAIR) if the pre-operative synovial fluid cultures are negative or if the cultures grow an easily treatable organism (Figure 109-3).[93,107,109] The treatment of choice for most patients is a two-stage process involving removal of the infected prosthesis and débridement of infected bone, stabilization of the joint by using an antibiotic-impregnated methyl-methacrylate spacer, and 6 weeks of intravenous antibiotics (first stage), followed by reimplantation of a second orthopedic implant (second stage). Using this approach, the success rate is approximately 72% to 95%; the success rate is slightly higher for hip versus knee arthroplasties. Risk factors for treatment failure include prior joint revision, presence of lymphedema with infection, rheumatoid arthritis, presence of a sinus tract, and infection with MRSA.[110] Rarely, antibiotic treatment is continued indefinitely in a patient in whom the risk of removing the infected prosthesis is too great, the prosthesis is not loose, and the organism responsible for the infection can be reasonably suppressed by the use of an oral antibiotic agent.[111]

The pathogenesis of bacterial infection in prosthetic joints is complex. Anatomic, virulence, and host factors affect prognosis and approach to therapy. An understanding of these interactions may lead to novel therapeutic and preventive strategies, such as vaccines against capsule antigens or surface adhesins in patients undergoing elective joint replacements.

## Prevention of Prosthetic Joint Infections

There is consensus that pre-operative evaluation of a patient for occult infection, such as periodontal disease, is warranted, and corrective steps to eradicate any infection are essential before joint replacement. There is also consensus that perioperative antibiotic prophylaxis significantly reduces the rate of early post-operative infection, and this practice is routine. Until recently, the role of antibiotic prophylaxis to prevent late prosthetic joint infection before diagnostic or therapeutic procedures that lead to transient bacteremia, especially dental treatment, has been controversial. Two case-controlled studies determined that there was no increased risk of infection of prosthetic joints following low- or high-risk dental procedures.[112,113] A position paper from the American Dental Association and the American Academy of Orthopedic Surgeons published in 2013 stated that there was no convincing evidence to support the routine use of prophylactic antibiotics in patients with prosthetic joints who undergo dental procedures.[114]

The incidence of late infection of a prosthetic joint as a result of procedure-related bacteremia is extremely low—10 to 100 cases per 100,000 patients with total joint replacement per year. The cost of providing antibiotic prophylaxis to all patients with prosthetic joints before all procedures that are associated with transient bacteremia is substantial. The efficacy of such antibiotic prophylaxis is not proven. Cost-effective analyses had mixed results.[115] These discrepancies are due to the lack of reliable data and the different assumptions used in the calculations. In the patient with the greatest risk of infection, an invasive procedure that leads to bacteremia sometimes can result in an infected total joint replacement. Counseling these patients on the risks and benefits of antibiotic prophylaxis would lead to an informed decision on which the patient and the physician can agree.

There is substantial evidence that there is an increased risk of orthopedic infection associated with the use of biologic agents that interfere with TNF inhibitors and IL-6. A retrospective analysis of 10 cases of post-operative infections showed the use of a TNF inhibitor was significantly associated with the development of a serious infection (odds ratio, 4.4).[116] A meta-analysis of the clinical literature on TNF inhibitors through 2005 found an increased risk of

**TABLE 109-8** Factors That Might Portend a Poor Outcome in Septic Arthritis

| |
|---|
| Older age |
| Pre-existing arthritis, especially rheumatoid arthritis, but also osteoarthritis and tophaceous gout |
| Presence of synthetic material (e.g., total joint replacement) |
| Delay in diagnosis or long duration of symptoms before seeking medical attention |
| Polyarticular infection, especially if >3 joints and small hand joints are affected |
| Presence of bacteremia |
| Infection caused by virulent or difficult-to-treat organisms (e.g., *Staphylococcus aureus, Pseudomonas aeruginosa,* or some Gram-negative bacilli) |
| Patients receiving immunosuppressive therapy |
| Serious underlying comorbidities (e.g., liver, kidney, or heart diseases) |
| Peripheral leukocytosis at presentation |
| Worsening renal function |

Data from Christodoulou C, Gordon P, Coakley G: Polyarticular septic arthritis. *BMJ* 333:1107-1108, 2006; Shinefield H, Black S, Fattom A, et al: Use of a *Staphylococcus aureus* conjugate vaccine in patients receiving hemodialysis. *N Engl J Med* 346:491–496, 2002; and Shmerling RH, Delbanco TL, Tosteson ANA, et al: Synovial fluid tests: what should be ordered? *JAMA* 264:1009–1014, 1990.

serious infection.[117] Guidelines from both the American College of Rheumatology and the British Society for Rheumatology recommend discontinuing TNF inhibitors around the time of elective arthroplasty surgery revision.[118,119] The risks and benefits must be weighed carefully, and the patients must be fully informed on how these agents should be used on a case-by-case basis.

## CONCLUSION

In the 21st century, patients with septic arthritis as a group are becoming older, with more risk factors for infection and more comorbidities. The number of patients with prosthetic joints is increasing while the population ages and people live longer. It is thus not surprising to see more cases of native and prosthetic joint infections. The organisms causing those infections have not changed significantly, however. Staphylococci (44% to 66%) are still the dominant organisms, followed by streptococci (18% to 28%) and Gram-negative bacilli (9% to 19%).[5] The emerging challenges in the treatment of septic arthritis are how to improve outcome, how to deal with resistant organisms, and how to overcome host factors that portend a poor prognosis.

The outcome of treated septic arthritis can be measured as mortality, as the functional outcome of the infected joint, or as short-term and long-term outcomes. Among the survivors, loss of articular cartilage, loss of motion, or increase in pain in the affected joint would be considered poor functional outcomes. Loss of the limb to infection and need for surgery to fuse the joint or restore function are also poor outcomes. Most studies report the outcome at the time of hospital discharge, and long-term data on adults with septic arthritis are unavailable. The rate of development of degenerative joint disease, the rate of relapse or recurrence of infection, and the rate of progression of functional impairment in the affected joint over time have not been well studied.

Many retrospective studies have characterized features that may increase the chance of a poor outcome at the time of hospital discharge (Table 109-8).[14,43,120] One prospective community-based study of adults and children found poor joint outcome in 33% of survivors among 154 patients with bacterial arthritis and noted older age, pre-existing joint disease, and an infected joint containing synthetic material as negative prognostic factors by univariate analysis.[120] These investigators noted no association between poor outcome and young age, comorbidity, immunosuppressive medication, functional class, multiple infected joints, type of organism, or treatment delay. In a large retrospective study from the United Kingdom on the outcome of 243 patients, 11.5% died secondary to septic arthritis, and additional morbidity was noted in 31.6% of patients. Multivariate analysis suggests that important predictors of death are confusion at presentation, age 65 years or older, multiple joint sepsis, and involvement of the elbow joint. Predictors of morbidity were age 65 years or older, diabetes mellitus, open surgical drainage, and Gram-positive infections other than *S. aureus*.[51]

CHAPTER 110

# Lyme Disease

Linda K. Bockenstedt

**KEY POINTS**

- Lyme disease is caused by infection with tick-transmitted spirochetes of the genus *Borrelia burgdorferi* sensu lato.
- Lyme disease has a characteristic pattern of signs and symptoms and usually begins with the expanding macular skin lesion erythema migrans.
- Earlier recognition and treatment has led to a decline in the incidence of carditis, acute neurologic disease, and late disease manifestations.
- Musculoskeletal manifestations occur in more than 50% of person and at all stages of infection, but frank arthritis is a sign of late disease.
- The diagnosis of Lyme disease should be suspected when a person who lives, works, or vacations in an endemic area is seen with signs and symptoms of *B. burgdorferi* infection.
- Two-tiered serologic tests (enzyme-linked immunosorbent assay and immunoblot) can be negative with early infection but become positive in most patients with infection of longer than a 1-month duration.
- Most patients are cured with 2 to 4 weeks of antibiotic therapy, although the time to disease resolution may extend beyond the duration of therapy, and irreversible tissue damage may occur.
- Antibiotic-refractory arthritis occurs in less than 10% of patients with Lyme arthritis, responds to disease-modifying anti-rheumatic drugs, and typically resolves within 5 years.
- Post–Lyme disease syndrome after antibiotic treatment for Lyme disease occurs in a minority of patients. *B. burgdorferi* cannot be detected in these patients, and controlled treatment trials show no benefit of prolonged antibiotic therapy over placebo.

Lyme disease is a multisystem disorder caused by the tick-borne spirochete *Borrelia burgdorferi*.[1] The disease first came to medical attention in the United States in the late 1970s with the investigation of a clustering of cases of juvenile arthritis in the region of Lyme, Connecticut.[2] A characteristic skin rash, described as single or multiple expanding red macules, often heralded the onset of arthritis. This rash, termed *erythema migrans* (EM), had been linked in Europe to the bite of *Ixodes* ticks and the subsequent development of neurologic abnormalities.[3] Further investigation revealed that arthritis was one manifestation of a systemic disorder affecting the skin, heart, joints, and nervous system. In 1982, Burgdorfer isolated the causative agent, the spirochete *B. burgdorferi*, from *Ixodes* ticks.[4] Demonstration that antibodies to this organism developed in patients with Lyme disease and its eventual culture from skin and cerebrospinal fluid (CSF) confirmed the infectious etiology of the disorder.[5] It is now the most common vector-borne disease in the United States.[1]

## ECOLOGY AND EPIDEMIOLOGY OF LYME DISEASE

Lyme disease has a worldwide distribution, with most cases reported in North America, Europe, and Asia.[6,7] On each of these continents, hard-shelled ticks of the *Ixodes* family are the only known vectors for the disease. Other arthropods and blood-sucking insects such as mosquitos cannot transmit the infection. The incidence of Lyme disease varies geographically and is determined by the prevalence of *B. burgdorferi*–infected ticks. In the United States, cases of Lyme disease have been reported in all 50 states and the District of Columbia, but most are clustered in the Northeast and mid-Atlantic region, upper Midwest, and northern California. Cases of Lyme disease outside these regions are mostly acquired after travel to highly endemic areas. In 2014, 25,359 confirmed and 8102 probable cases were reported to the Centers for Disease Control and Prevention, with 96% of confirmed cases originating from 14 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia, and Wisconsin.[8] The number of reported cases is approximately 10-fold less than the actual case incidence, which is estimated to be approximately 300,000 cases annually.[9]

The spirochetes associated with Lyme disease reside within the genus *B. burgdorferi* sensu lato (sl), and the vast majority of cases are caused by *B. burgdorferi* sensu stricto (ss), *Borrelia garinii*, and *Borrelia afzelii*.[6,7] All three genospecies can be found in Europe, whereas *B. burgdorferi* ss is the main species found in North America. Variation among the genospecies may account for the differences in clinical expression of Lyme disease between the two continents: *B. garinii* is associated with neurologic disease, *B. afzelii* is associated with late skin involvement, and *B. burgdorferi* ss is associated with arthritis.[1,6] Because of the prominence of musculoskeletal manifestations with *B. burgdorferi* ss infection, this chapter focuses mainly on Lyme disease in North America.

## TICKS AND LYME DISEASE

Lyme disease is found primarily in temperate climates where an enzootic cycle maintaining *B. burgdorferi* in *Ixodes* ticks

is established.[6,7] *Ixodes* ticks have a 2-year life span in which they pass through three developmental stages—larva, nymph, and adult—feeding only once per stage.[10] *B. burgdorferi* is not passed transovarially and is maintained by passage between reservoir hosts and ticks. Small rodents are the main reservoirs for *B. burgdorferi* ss and *B. afzelii*, whereas birds are the principal haven for *B. garinii*.[6]

Larvae acquire *B. burgdorferi* after feeding on an infected mammal in early spring and then molt to nymphs, which lay dormant until the following late spring and summer. The peak incidence of Lyme disease is in the summer months, when humans come in contact with questing nymphs.[11] Engorged nymphs molt into adult ticks, which feed mainly on deer. *B. burgdorferi* does not persist in deer, which serve to maintain and propagate the tick population.

## PATHOGENESIS

### *Borrelia burgdorferi* Invasion of the Mammalian Host

The onset of tick feeding signals *B. burgdorferi* residing in the tick midgut to undergo global changes in gene expression, multiply, and migrate to the salivary glands, where they pass with saliva into the blood meal host.[12,13] Although spirochetes expand greatly in numbers in the tick midgut, relatively few spirochetes—estimated in the hundreds—are deposited at the bite site, a process that takes at least 24 hours.[14] After establishing infection in the skin, spirochetes can disseminate via the bloodstream to infect any organ system. Spirochete virulence, growth conditions that allow persistence at a particular site, and host factors that modulate the inflammatory response determine disease expression.

*B. burgdorferi* has no known virulence factors common to other bacterial pathogens that may explain the pathogenesis of Lyme disease.[15,16] Its genome is remarkably rich in genes encoding putative lipoproteins, only a handful of which have been studied in detail. Outer surface protein (Osp) A is a midgut adhesin required for spirochete infection of ticks.[17] Osp C is essential for initial infection of the mammal but is dispensable after spirochetes have disseminated and colonized other tissue.[18] To do so, *B. burgdorferi* harnesses host plasmin to move through tissues[19,20] and expresses adhesins, including decorin-binding proteins A and B, BBK32, and p66, which allow it to bind to extracellular matrix proteins (ECM) and integrins on cells.[21] *B. burgdorferi* expresses a protease with aggrecanase activity and induces the host expression of matrix metalloproteinases, which degrade ECMs.[22] Expression of VlsE, an Osp that undergoes antigenic variation, is required for infection to persist.[23,24]

### Pathology of Lyme Disease

Because few spirochetes can be seen in infected tissues, and *B. burgdorferi* secretes no known toxins, the host inflammatory response is believed to underlie the pathology seen in Lyme disease. Engagement of adaptive immunity is present at the earliest clinical sign of Lyme disease (EM).[25,26] Histopathologic studies of EM lesions, cardiac tissue, synovial biopsy specimens, and limited nervous system tissue (meninges, spinal cord, and nerve roots) reveal varying degrees of monocytic and lymphoplasmacytic infiltrates, especially perivascular, that stain positively for cell surface markers for macrophages, T cells, and B cells.[27,28] The proportions of responding immune cells differ among EM, CSF, and synovial fluid samples, suggesting a tissue-specific immune response to *B. burgdorferi* infection. In particular, synovial fluid exhibits elevated leukocyte counts, whereas a lymphocytic pleocytosis is seen in CSF of patients with central nervous system (CNS) involvement. Lyme arthritis synovium resembles that of rheumatoid arthritis, with chronic inflammation mediated by mononuclear cell infiltration and pseudolymphoid follicles formed by T cells, B cells, and plasma cells. In the synovium and, less commonly, the epineural area, perivascular infiltrates can be associated with endarteritis obliterans.

### Immune Response to *Borrelia burgdorferi*

Innate immune cells respond to *B. burgdorferi* through engagement of the Toll-like receptor (TLR) family of pattern recognition receptors, especially TLR2/TLR1 heterodimers (lipoproteins), TLR5 (flagellin), TLR7 and TLR8 (RNA), and TLR9 (spirochete DNA).[29-33] As a consequence, pro-inflammatory cytokines, including IL-1β, TNF, and type I interferons, are produced that recruit inflammatory cells to the site of infection.[33] *B. burgdorferi* also induces matrix metalloproteinase expression in tissues through TLR-dependent and non–TLR-dependent pathways.[34] Other pattern recognition receptors may be engaged by *B. burgdorferi* after its ingestion by phagocytes, including the intra-cellular NOD2 receptors, which respond to peptidoglycan and potentiate the inflammatory response in vitro.[35]

Humoral immunity is a key host defense against *B. burgdorferi* infection. *B. burgdorferi* lipoproteins are B cell mitogens, and antibodies that arise in the absence of T cell help are sufficient to resolve inflammation and prevent challenge infection in the mouse model of Lyme borreliosis.[36,37] With the induction of adaptive immunity, immunoglobulin (Ig)G-containing immune complexes can be found in the serum of patients with Lyme disease and are concentrated in the joints of patients in whom Lyme arthritis develops.[38] The B cell–recruiting chemokine CXCL13 can be found in the CSF of patients with neuroborreliosis[39]; B cells constitute approximately 15% of the nucleated cells, an order of magnitude higher than in other infectious and inflammatory neurologic diseases.[40] Intrathecal production of *B. burgdorferi*–specific antibodies is found and some of these antibodies can also bind neural antigens.[41-45]

*B. burgdorferi* infection primes $CD4^+$ and $CD8^+$ T cells, and the predominance of T helper (Th) type 1 responses correlates with more severe arthritis and neuroborreliosis.[46,47] Th17 cells are also involved. In the CSF, T cells represent more than 60% of the responding cells with $CD4^+$ Th1 cells a majority; approximately half of patients with neurologic involvement have elevated levels of IL-17.[48] *B. burgdorferi* neutrophil-activating protein A is abundant in synovial fluid and can elicit IL-17 from synovial fluid T cells ex vivo.[49] Synovial fluid also contains other T cell subsets, including $CD25^+Foxp3^+$ T cells, γδ T cells, and natural killer (NK) T cells, which may regulate the inflammatory response.[28,50-52]

## Mechanisms of Spirochete Persistence

When visualized in vivo, *B. burgdorferi* resides primarily in the ECM in connective tissue.[27,53] Despite occasional sightings of spirochetes inside cells,[54] an intra-cellular phase of the *B. burgdorferi* life cycle has not been shown. *B. burgdorferi* uses immune evasion strategies of an extracellular pathogen, which are directed toward deterring phagocyte ingestion and antibody- and complement-mediated lysis.[1] *B. burgdorferi* expresses Erp and complement regulator–acquiring surface proteins that bind host factor H to prevent complement-mediated lysis.[55-57] To impede antibody-mediated clearance, *B. burgdorferi* undergoes antigenic variation[23,24] and reduces expression of lipoproteins as infection progresses.[58] The *vlsE* gene undergoes random rearrangement of its expression locus, producing antigenically distinct variants of VlsE.[23] In the chronic phase of *B. burgdorferi* infection in mice, spirochetes can be visualized in the ECM of connective tissue, especially in the skin, without an associated inflammatory response.[59]

# CLINICAL FEATURES

Lyme disease occurs in stages that reflect the immune response to the spirochete while it establishes infection in the skin and later disseminates to distant organ sites (Table 110-1). Presenting clinical manifestations depend on the stage of the illness in which patients first seek medical attention. A characteristic feature of Lyme disease is that clinical signs can resolve without specific therapy, and patients may be seen in later stages of the illness without exhibiting signs of early disease.

## Early Localized Infection

The hallmark of Lyme disease is the skin lesion EM, which is present in approximately 80% of patients (Figure 110-1).[60] The lesion arises within 1 month (median, 7 to 10 days) at the tick-bite site, which is often in skin folds or where clothes bind in adults and around the hairline in children. EM begins as a red macule that expands at the rate of 2 to 3 cm/day, enlarging to more than 70 cm in diameter. Characteristic lesions greater than 5 cm in diameter in an appropriate clinical setting are sufficient for establishing the diagnosis of Lyme disease.[61] EM most often manifests with uniform erythema, but central clearing can occur in larger lesions, producing a "bull's eye" appearance (see Figure 110-1B). Vesicular or necrotic centers are rarer (see Figure 110-1D), but even these EM lesions have relatively few symptoms other than a tingling or burning sensation. Intense pruritus or pain is unusual and should raise concern for alternative diagnoses.

EM may be accompanied by systemic flulike symptoms, including low-grade fever, malaise, neck pain or stiffness, arthralgias, and myalgias.[62,63] Particularly severe systemic symptoms should alert the physician to possible coinfection with another tick-borne pathogen such as *Babesia microti* or *Anaplasma phagocytophilum* (the agent of human granulocytic anaplasmosis, formerly known as *human granulocytic ehrlichiosis*). Lyme disease can also manifest with systemic symptoms alone.[64,65] Absence of upper respiratory or gastrointestinal symptoms may help distinguish Lyme disease from common viral infections. Musculoskeletal complaints and debilitating fatigue associated with Lyme disease should be distinguished from fibromyalgia and chronic fatigue syndrome, which are typically more insidious in onset and are not associated with objective findings or laboratory abnormalities.

Southern tick–associated rash illness (STARI) can produce a skin lesion similar to the bull's eye form of EM.[66] STARI is associated with the bite of the Lone Star tick, *Amblyomma americanum*, which is endemic to the southeastern and south-central states, but also can be found as far north as Maine or west as central Texas and Oklahoma. Systemic symptoms can accompany the STARI rash, but extracutaneous disease does not occur. The etiology of STARI is unknown; studies indicate it is not caused by *B. burgdorferi*. Antibiotics resolve EM and STARI, but STARI patients recover more quickly from systemic symptoms than patients with Lyme disease.

**TABLE 110-1** Clinical Manifestations of Lyme Disease

| |
|---|
| **Early Localized Infection** |
| Occurs 3 to 30 days after tick bite |
| EM in 80%-90% of patients; single lesion, occasionally associated with fever, malaise, neck pain or stiffness, arthralgias and myalgias |
| Systemic symptoms noted above in the absence of EM during summer months |
| Borrelial lymphocytoma (rare, seen primarily in Europe) |
| **Early Disseminated Infection** |
| Occurs weeks to months after tick bite |
| Profound malaise and fatigue common |
| Multiple EM lesions with systemic symptoms similar to early localized infection |
| Musculoskeletal<br>Migratory polyarthralgias and myalgias |
| Cardiac<br>Carditis (<3% of untreated patients)<br>Varying degrees of atrioventricular nodal block<br>Mild myopericarditis |
| Neurologic (<10% of untreated patients)<br>Cranial neuropathies (especially facial nerve palsy)<br>Lymphocytic meningitis<br>Radiculoneuropathies<br>Encephalomyelitis |
| **Late Disease** |
| Occurs months to years after tick bite |
| Arthritis (<10% of patients)<br>Acute monoarticular or migratory pauciarticular inflammatory arthritis, usually involving the knee<br>Chronic antibiotic-refractory arthritis (<10% of patients with arthritis) |
| Neurologic (rare)<br>Peripheral neuropathies<br>Mild encephalopathy<br>Encephalomyelitis (primarily seen in Europe) |
| Skin<br>Acrodermatitis chronica atrophicans (primarily seen in Europe) |

EM, Erythema migrans.

## Early Disseminated Infection

Disseminated *B. burgdorferi* infection occurs within weeks of the tick bite. At this stage, clinically apparent disease is

**Figure 110-1** Erythema migrans rash of Lyme disease. **A,** Typical macular lesion on left shoulder. **B,** Bull's eye lesion on lateral thigh with central punctum. **C,** Multiple lesions on back. **D,** Lesion with vesicular center on posterior thigh. *(Courtesy Juan Salazar, MD, University of Connecticut Health Center.)*

usually seen in the skin, heart, or nervous system. Patients with disseminated infection have debilitating fatigue and can appear ill. Specific localizing signs and symptoms may fluctuate, but profound fatigue is a consistent complaint.

### Skin Disease

Fifty percent of patients with untreated Lyme disease experience multiple EM lesions, a sign of disseminated infection (see Figure 110-1C).[60] Secondary lesions are typically smaller and can occur anywhere on the body, but they are most noticeable on the trunk. The lesions usually appear as flat macules and can develop partial central clearing. EM lesions may be accompanied by migratory muscle, joint, and periarticular pain that lasts hours to days, but arthritis does not appear until months after the initial infection.

### Cardiac Disease

Cardiac involvement is clinically apparent in less than 1% of patients with Lyme disease.[1] It most often occurs within the first 2 months of infection and manifests as varying degrees of atrioventricular block, occasionally accompanied by mild myopericarditis.[67,68] Sudden death can occur.[69-71] Electrophysiologic studies have mapped the conduction defect to the area above the bundle of His and involving the atrioventricular node, although multiple levels can be affected. Overt congestive heart failure is rare, and chronic cardiomyopathy, reported in Europe, has not been documented in the United States.[72] Patients with Lyme carditis often have a history of EM and may have concomitant arthralgia and myalgia at the time of presentation. Absence of valvular heart disease helps distinguish Lyme carditis from acute rheumatic fever, and prominent myocardial dysfunction or pericardial involvement should suggest other infectious etiologies.

### Nervous System Involvement

Acute neurologic Lyme disease occurs in less than 10% of patients and most commonly manifests as cranial nerve palsy or meningitis, although radiculopathy and encephalomyelitis are also occasionally seen.[73-77] Cranial palsy occurs in 8% of cases and usually affects the seventh nerve, resulting in unilateral or bilateral facial palsy. Even in endemic areas, however, onset of seventh nerve palsy in the nonwinter months is caused by *B. burgdorferi* infection in only 25% of cases.[78] Bilateral facial palsy is seen in only a few other conditions—Guillain-Barré syndrome, HIV infection, sarcoidosis, and other causes of chronic meningitis—all of which are readily distinguished from Lyme disease. Rarely, other cranial nerves (III, IV, V, VI, or VIII) may be involved. Lyme meningitis manifests with fever, headache, and stiff neck similar to viral meningitis, along with a CSF lymphocytosis and elevated protein.[76] In children, meningitis may occur with EM, cranial nerve involvement, and increased

intracranial pressure (papilledema), which is rare in adults.[75,79] Lyme radiculopathy typically manifests as pain, weakness, numbness, and reflex loss in a dermatomal distribution, resembling mechanical radiculopathies.[74] Untreated Lyme radiculopathy can progress to become bilateral, which helps distinguish it from mechanical disease. When truncal involvement causes unilateral chest or abdominal pain, Lyme radiculopathy is often mistaken for visceral disease or early herpes zoster before the development of vesicular lesions.

### Other Organ System Involvement

A variety of other organs can exhibit pathology with disseminated *B. burgdorferi* infection, including the eye (keratitis), the ear (sensorineural hearing loss), the liver (hepatitis), the spleen (necrosis), skeletal muscle (myositis), and subcutaneous tissue (panniculitis).[80] In general, more classic manifestations of Lyme disease are present concurrently or have been present in the recent past to suggest the diagnosis.

## Late Disease

Months after the onset of infection, untreated patients can develop late manifestations of Lyme disease, usually involving the joints (discussed separately later), nervous system, and the skin. At this stage of infection, two-tier (enzyme-linked immunosorbent assay [ELISA] and IgG immunoblot) serologic testing for *B. burgdorferi* should be positive.

### Neurologic Disease

Late neurologic Lyme disease is now rare; patients may be seen with encephalomyelitis, peripheral neuropathy, or encephalopathy.[81,82] Encephalomyelitis, seen predominantly in Europe with *B. garinii* infection, is a slowly progressive, unifocal, or multifocal inflammatory disease of the CNS, with increased T2 signals in the white matter on MRI. CSF examination often reveals a lymphocytic pleocytosis, elevated protein, and normal glucose, and serum IgG to *B. burgdorferi* and intrathecal antibody production can be found. These findings help distinguish Lyme encephalomyelitis from multiple sclerosis, which may rarely be associated with positive IgG reactivity to *B. burgdorferi* in serum and CSF samples, but there is no intrathecal antibody production.[82,83] Multiple sclerosis patients with positive Lyme serologies do not respond to antibiotics used for neurologic Lyme disease.

Late peripheral nervous system involvement manifests as a mild sensorimotor neuropathy in a "stocking and glove" distribution, with evidence of a mild confluent mononeuritis multiplex on electrophysiologic studies.[74] Patients may have intermittent limb paresthesias and occasionally radicular pain. The most common finding on physical examination is reduced vibratory sensation in the lower extremities. Serum IgG to *B. burgdorferi* should be present, but CSF examination is normal. Patients with this form of neuropathy should be evaluated for other infectious diseases (syphilis, human immunodeficiency virus, and hepatitis C virus); metabolic disorders (especially vitamin $B_{12}$ deficiency, diabetes mellitus, and thyroid disease); and autoimmune diseases.

Patients with Lyme encephalopathy complain of memory impairment and cognitive dysfunction that are best shown by formal neuropsychological testing.[81,84,85] Occasionally, patients may have CSF abnormalities with elevated protein, lymphocytic pleocytosis, and intrathecal antibody to *B. burgdorferi*, but CSF examination can also be normal. Serum IgG to *B. burgdorferi* should be present, however, to consider the diagnosis. The mild cognitive dysfunction seen in patients with Lyme encephalopathy must be distinguished from neurocognitive deficits secondary to chronic stress, sleep deprivation, fibromyalgia, chronic fatigue syndrome, or aging. As for any chronic encephalopathy, toxic-metabolic causes should be excluded. Brain imaging studies are generally normal or show only nonspecific abnormalities and are not useful in establishing a diagnosis of encephalopathy associated with Lyme disease.

### Skin Disease

The late-skin lesion acrodermatitis chronica atrophicans (ACA) is found mainly in Europe because of its association with *B. afzelii* infection, although any *B. burgdorferi* species can cause the lesion.[86] ACA develops insidiously over years and is most often found on an extremity. It begins as a unilateral bluish red discoloration and swelling, which evolves to atrophic, cellophane-like skin with prominent appearance of the blood vessels. Allodynia is considered a characteristic symptom of the skin lesion. Approximately 60% of patients also have a peripheral sensory neuropathy affecting the involved extremity. A prominent lymphoplasmacytic infiltrate is shown on the skin biopsy specimen. Antibiotics can lead to improvement in pain and swelling, but atrophic skin remains.

## LYME ARTHRITIS AND OTHER MUSCULOSKELETAL MANIFESTATIONS OF LYME DISEASE

Musculoskeletal symptoms are common in all stages of Lyme disease and include migratory pain in joints, tendons, bursae, and muscles.[1,87] Typically, musculoskeletal pain affects one or two sites at a time, lasts only hours to a few days at any one location, and is associated with significant fatigue. The incidence of frank arthritis has declined from 50% in early studies to less than 10% in more recent years.[28] ELISA and IgG immunoblot for *B. burgdorferi* are positive when arthritis appears, and *B. burgdorferi* DNA can be detected by polymerase chain reaction (PCR) in synovium and synovial fluid even though cultures are negative. Although Lyme arthritis can resemble pauciarticular juvenile arthritis or reactive arthritis, patients generally test negative for anti-nuclear antigen (ANA), rheumatoid factor, and anti-citrullinated protein antibodies and do not have an increased frequency of human leukocyte antigen (HLA)-B27 alleles. Joint fluid analysis and synovial histopathology cannot distinguish these entities. Axial and sacroiliac joint involvement is not a feature of Lyme disease, but enthesitis can be seen.

Arthritis usually begins months or years after *B. burgdorferi* infection (average 6 months) and is pre-dated by migratory arthralgias in half of patients.[87] The most typical pattern is a monoarticular or oligoarticular arthritis involving one

or a few large joints (≤5 total), with the knee affected in 80% of cases. Joints are warm with large effusions, often greater than 100 mL in the knee, but comparatively little pain. Synovial fluid is usually inflammatory with white blood cell counts ranging from approximately 500 to more than 100,000/mm$^3$ (median ~ 25,000/mm$^3$), with a predominance of neutrophils. Children with Lyme arthritis may present more acutely with fever and a painful, swollen joint resembling septic arthritis.[88,89] Large effusions can lead to Baker's cyst formation and rupture. The temporomandibular joint is also frequently involved.[87] Other joints commonly affected include the shoulder, ankle, elbow, wrist, and hip. Lyme arthritis is often intermittent, with episodes lasting a few weeks to months. Recurrent episodes are notable for smaller effusions and progressive synovial hypertrophy, bony erosion, and cartilage destruction. A small percentage (<10%) of patients with intermittent arthritis settle into a pattern of chronic arthritis, affecting only a single joint. Inflammation of a single joint that persists for more than 12 months would be an unusual presenting manifestation of Lyme arthritis, as is the prominent involvement of small joints.

The natural history of Lyme arthritis suggests that it is a self-limited disorder. In the late 1970s, before the use of antibiotics for Lyme disease, 21 patients who were seen with EM and later were diagnosed with Lyme arthritis were followed up for 1 to 8 years without anti-microbial therapy.[87] Six patients had only a single episode of arthritis, and the remaining 15 had recurrent episodes that decreased in frequency during the study period. On average, the number of patients who continued to experience episodes of arthritis decreased by 10% to 20% each year. Similar results were found in children in whom antibiotic treatment for arthritis was delayed 4 years.[90]

### Antibiotic-Refractory Lyme Arthritis

Approximately 10% of patients treated with standard antibiotic regimens for Lyme arthritis have persistent joint inflammation and proliferative synovitis that does not respond to further anti-microbial therapy.[28] The pathogenesis of "antibiotic-refractory" Lyme arthritis is unknown but may be to the result of persistent spirochetes or their antigens, infection-induced autoimmunity, or inadequate regulation of the inflammatory response.[1] Spirochete strains that have a greater propensity to become blood-borne have been found at higher rates in patients in whom antibiotic-refractory arthritis develops.[91-93] Although spirochete DNA can be detected in synovial fluid for months after treatment, its presence does not predict arthritis relapse rate or persistence.[94] Experiments in the mouse model of Lyme borreliosis suggest that spirochete debris, including *B. burgdorferi* DNA, can persist near cartilage and in the entheses for extended periods after infectious spirochetes have been killed with antibiotics, particularly when the initial pathogen burden was high.[53] Genetic polymorphisms may contribute to the rate at which inflammation subsides after viable spirochetes have been eliminated. A single nucleotide polymorphism in TLR1 (TLR1 1805 GG) was found to be more prevalent among patients who developed antibiotic-refractory Lyme arthritis.[95] Recently, deficiency in the lysosomal enzyme β-glucuronidase (GusB) was found to underlie the genetic susceptibility of the C3H mouse strain to more severe Lyme arthritis; deficiency in GusB also exacerbates arthritis in a serum transfer model of inflammatory arthritis.[96] GusB functions to degrade glycosaminoglycan (GAGs) that are produced in higher abundance during inflammation. GAGs directly activate TLRs, and their accumulation could potentiate and prolong inflammation.

A genetic predisposition to antibiotic-refractory Lyme arthritis had been suggested in earlier studies that found an association with the rheumatoid arthritis–related alleles HLA-DRB1*0401, HLA-DRB1*0101, and HLA-DRB1*0404.[97] A search for *B. burgdorferi* antigens that could be presented by these HLA molecules and potentiate inflammation through molecular mimicry initially centered on OspA because of the high prevalence of OspA-specific B cell and T cell responses in patients with antibiotic-refractory arthritis[28,97,98] Although an Osp A peptide was found to have homology with the adhesion molecule human leukocyte function–associated antigen 1 (LFA-1),[99] the corresponding LFA-1 peptide did not elicit the Th1 cytokine IFN-γ normally found in antibiotic-refractory arthritis.[100] More recently, linked T and B cell responses to peptides of epidermal cell growth factor have been found in about 50% of patients with antibiotic-refractory Lyme arthritis.[101] Antibodies to endothelial cell growth factor (ECGF) correlate with the presence of obliterative vasculopathy.[102] Deficiencies in regulation of the immune response have been reported. CD25$^+$FoxP3$^+$ T regulatory cells are reduced in number in the synovial fluid of patients with antibiotic-refractory Lyme arthritis.[50,103] Invariant NK T cells, which may have immunodulatory properties, were notably absent in one study.[52] If autoimmunity is responsible for antibiotic-refractory Lyme arthritis, it must eventually succumb to immune regulation because even this form of Lyme arthritis generally resolves within 4 to 5 years.[87,104]

## DIAGNOSIS

The diagnosis of Lyme disease should be considered in individuals who are seen with an appropriate clinical history and who have a reasonable risk of exposure to *B. burgdorferi*–infected ticks (Figure 110-2).[41] Supporting serologic evidence is necessary to secure the diagnosis at all stages of infection except when EM is present.[61] Routine laboratory tests are nonspecific, with some patients exhibiting mildly elevated white blood cell (neutrophil) counts, erythrocyte sedimentation rates, and liver function tests. Culture or microscopic visualization of spirochetes in clinical samples is not sensitive enough for routine use in diagnosis. Culture of a skin biopsy specimen taken from the leading margin of an EM lesion is an exception, with *B. burgdorferi* detected in more than 40% of samples. The validity of a novel serum culture assay for detecting *B. burgdorferi* in blood samples has been questioned and should not be used.[105,106]

### Serologic Testing

Detection of antibodies to *B. burgdorferi* is the mainstay of laboratory testing for Lyme disease.[41] Presence of antibodies to *B. burgdorferi* at best indicates previous exposure to the organism, however, and should not be considered evidence of active infection. In nonendemic areas, approximately 5%

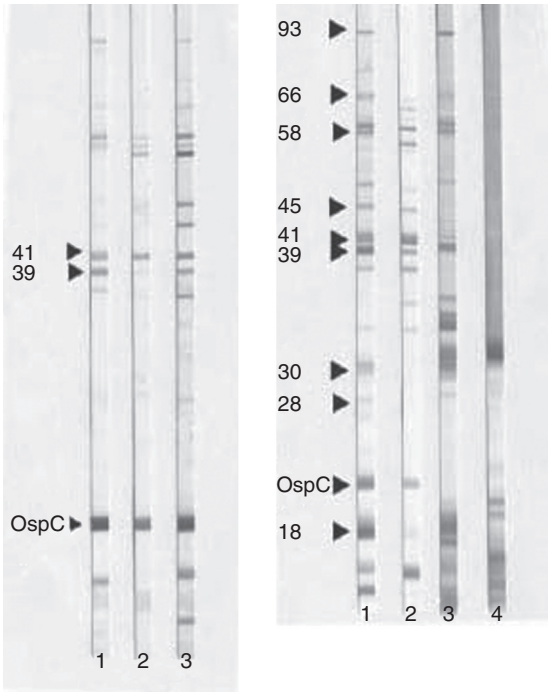

**Figure 110-2** *Left,* Selected IgM immunoblot reactivities. *Lane 1,* Serum band locator control showing several bands including the significant 41 kDa protein, 39 kDa protein, and OspC *(arrowheads). Lane 2,* Serum sample from a patient with early Lyme borreliosis with erythema migrans. *Lane 3,* Serum sample from a patient with early disseminated Lyme borreliosis with multiple erythema migrans lesions. Lane 2,* Serum sample from a patient with early disseminated Lyme borreliosis with neurologic involvement. *Lane 3,* Serum sample from a patient with Lyme arthritis. *Lane 4,* Serum sample from an individual who received three doses of OspA vaccine; note the strong reactivity with OspA (31 kDa) and other antigens below OspC. *(From Aguero-Rosenfeld ME, Wang G, Schwartz I, et al: Diagnosis of Lyme borreliosis.* Clin Microbiol Rev *18:484–509, 2005.)*

of normal human serum samples yield positive results on serologic tests for Lyme disease. In endemic areas, asymptomatic IgG seroconversion to *B. burgdorferi* has been found in approximately 7% of patients.[107]

A two-tiered approach is recommended for detection of *B. burgdorferi*–specific antibodies.[108,109] An ELISA or an indirect immunofluorescence assay to detect IgM and IgG reactivity to *B. burgdorferi* should be used as an initial screening test, followed by an immunoblot (Western blot) to confirm that positive or equivocal results are due to antibodies that bind *B. burgdorferi* antigens. ELISA and immunofluorescence assays are highly sensitive tests but lack specificity because of cross-reactivity of antibodies to *B. burgdorferi* with other bacterial pathogens.[41] A positive or equivocal ELISA or immunofluorescence assay should be confirmed by immunoblot analysis of *B. burgdorferi* proteins (Table 110-2). Banding patterns characteristic of early infection include antibodies to the 41 kilodalton (kDa) flagellin protein and Osp C, which has a molecular weight ranging from 21 to 24 kDa depending on the *B. burgdorferi* strain used (see Figure 110-2). With disseminated infection, and especially with late Lyme disease, IgG reactivity to an expanding array of *B. burgdorferi* proteins can be seen (see Figure 110-2).

**TABLE 110-2** Criteria for Western Blot Interpretation in the Serologic Confirmation of Lyme Disease

| Duration of Disease | Isotype Tested | Criteria for Positive Test |
|---|---|---|
| 1 month or less | IgM | 2 of the following 3 bands are present: 23 kDa (OspC), 39 kDa (BmpA), and 41 kDa (Fla) |
| Greater than 1 month | IgG | 5 of 10 bands are present: 18 kDa, 21 kDa, 28 kDa, 30 kDa, 39 kDa, 41 kDa, 45 kDa, 58 kDa (not GroEL), 66 kDa, and 93 kDa |

Modified from Centers for Disease Control and Prevention: Recommendations for test performance and interpretation from the Second National Conference on Serologic Diagnosis of Lyme Disease. *MMWR Morb Mortal Wkly Rep* 44:590–591, 1995.

A peptide-based ELISA that uses a highly conserved invariant region of the VlsE protein, termed C6 (IR6), can be used in lieu of ELISA based on whole bacterial cell lysates.[110,111] This assay has increased sensitivity but slightly lower specificity in early infection when compared with the whole-cell lysate ELISA.[111] A positive or equivocal test should be confirmed with IgM and IgG immunoblots.

Two-tier testing for IgM and IgG should be performed for individuals with suspected Lyme disease and signs and symptoms of less than 1 month duration, whereas only IgG results should be considered for illnesses of longer duration.[108] Positive IgM serologies alone after 1 month of illness are most often false-positive tests, which occur in the setting of other infectious diseases (especially infectious mononucleosis and other spirochetal and tick-borne infections), rheumatoid arthritis (with or without rheumatoid factor), and conditions associated with a positive ANA (systemic lupus erythematosus).[112] No further testing is recommended if ELISA or immunofluorescence assay results are negative. Two-tier testing has overall sensitivities of 29% to 40% in EM during the acute phase; 29% to 78% for EM in the convalescent phase; and greater than 95% in neurologic, arthritis, and other manifestations of late disease.[41]

Some commercial laboratories have developed assays using recombinant antigens or use criteria for the interpretation of immunoblots that have not been validated.[113] For this reason, the Centers for Disease Control and Prevention advises using only validated tests approved by the U.S. Food and Drug Administration (FDA) for serologic diagnosis of Lyme disease.

After antibiotic therapy, IgM and IgG titers to *B. burgdorferi* measured by either whole cell ELISA or the C6 peptide ELISA (IgG only) generally decrease slowly but can remain positive for years.[114,115] Repeat serologic testing is not recommended as a means for assessing response to treatment.

## Antibodies to *Borrelia burgdorferi* in Cerebrospinal Fluid

In suspected cases of neuroborreliosis, intrathecal antibody production is usually assessed by measuring the ratio of IgG to *B. burgdorferi* in CSF and serum.[41,116] Intrathecal antibody

production is more commonly found in European neuroborreliosis than in North American Lyme disease, which may be the result of the higher prevalence of *B. garinii* in CNS infection than *B. burgdorferi* ss. Antibodies to *B. burgdorferi* may persist in CSF after treatment for Lyme disease and should not be used to assess efficacy of therapy.

### Polymerase Chain Reaction

PCR has been used to detect *B. burgdorferi* DNA in a variety of clinical specimens with variable success.[41,117] The greatest utility of PCR clinically is in Lyme arthritis, in which the sensitivity of PCR for detection of *B. burgdorferi* DNA is 85%.[118] In contrast, the sensitivity of PCR for detecting *B. burgdorferi* DNA in CSF is low and most often positive in patients with a CSF pleocytosis. PCR of urine specimens is not recommended because of documented nonspecific amplification of non–*B. burgdorferi* DNA targets.[41,113] Recently a novel two-step method for amplifying *B. burgdorferi* DNA was reported to detect the pathogen in two-thirds of blood specimens from patients with EM[119]; additional studies are needed to validate the method. PCR testing is useful for establishing exposure to *B. burgdorferi* but positive results are not necessarily a reflection of active infection, as *B. burgdorferi* DNA can persist for months after spirochetes are killed with antibiotics in vitro and in vivo.[53,94] There are currently no FDA-approved tests for PCR-based molecular techniques for detecting *B. burgdorferi* DNA in patient specimens.

### Other Tests

A urine antigen test, immunofluorescent staining for cell wall–deficient forms of *B. burgdorferi*, and lymphocyte transformation assays are offered by some commercial laboratories to aid in the diagnosis of Lyme disease. These tests have not been adequately validated for accuracy or clinical usefulness, and should not be used.[113]

### Imaging

Imaging studies have a limited role in the evaluation of patients with Lyme disease because no feature is sufficiently distinctive to confirm the diagnosis. Plain radiographs of arthritic joints show changes consistent with an inflammatory arthropathy, including joint effusions, synovial hypertrophy, periarticular osteoporosis, cartilage loss, bony erosions, and calcified entheses.[120] MRI of arthritic joints can confirm the radiographic findings and reveal associated myositis and adenopathy, which may be useful in distinguishing Lyme arthritis from septic arthritis in children.[121]

Cranial and spinal MRI findings in neuroborreliosis can reveal focal nodular lesions or patchy white matter lesions on T2-weighted images, consistent with inflammatory or demyelinating processes.[122-124] These lesions typically resolve after treatment for Lyme disease,[124] in some cases only after several years.[125] In patients with post–Lyme disease syndrome, cerebral MRI and the more sensitive technique of fluid-attenuated inversion recovery are normal in approximately 50% of cases or show nonspecific findings of small white-matter lesions.[126] Positron-emission tomography and single-photon emission computed tomography studies are often normal or show only nonspecific changes with subcortical and cortical hypoperfusion.[127,128]

## TREATMENT AND OUTCOME

Guidelines for the clinical assessment (Figure 110-3) and treatment (Table 110-3) of Lyme disease have been published.[129] Because many of the manifestations of Lyme disease resolve without specific therapy, the goal of antibiotic treatment is to hasten resolution of signs and symptoms and to prevent later clinical manifestations. Generally, oral antibiotics are sufficient therapy for EM, disseminated EM, uncomplicated facial palsy, mild carditis (first-degree atrioventricular block), and arthritis. Disseminated infection and late manifestations of Lyme disease may require longer courses of antibiotics, and there is often a greater lag time to symptom resolution compared with early disease. Doxycycline is the antibiotic of choice in non-pregnant adults and children aged 8 years and older because it is also effective against *A. phagocytophilum*, which may occur with early Lyme disease.[129] Amoxicillin and cefuroxime axetil are acceptable alternatives for the treatment of EM, facial palsy, and other non-neurologic manifestations of Lyme disease. Macrolide antibiotics are less effective than other antimicrobials and should be used only in individuals who cannot take doxycycline, amoxicillin, or cefuroxime axetil. First-generation cephalosporins are not effective therapy for Lyme disease.

Documented nervous system involvement (other than isolated facial palsy) and symptomatic cardiac involvement are the two main indications for intravenous antibiotic therapy.[129] Ceftriaxone administered intravenously for 2 to 4 weeks is the preferred anti-microbial, with parenteral cefotaxime or penicillin G acceptable alternatives. There is increasing evidence, however, that oral doxycycline, which is well absorbed and has a high CNS penetration, may be effective for meningitis or radiculopathy.[130-132] Lumbar puncture is recommended in individuals with cranial nerve palsies who have symptoms of meningeal irritation because a CSF pleocytosis would be an indication to treat with intravenous therapy. Asymptomatic CSF pleocytosis can occur in the setting of facial palsy and is not an indication for intravenous therapy. Repeat treatment is not recommended for chronic neurologic abnormalities, unless objective signs of relapse are present.

Patients with symptomatic cardiac involvement (chest pain, shortness of breath, syncope) or with significant conduction system disease (first-degree atrioventricular block with P-R intervals ≥0.3 msec, or second-degree or third-degree block) should be hospitalized for cardiac monitoring and intravenous antibiotic therapy. Consultation with a cardiologist is recommended, and placement of a temporary pacemaker may be necessary. Oral antibiotics can be substituted for intravenous antibiotics at the time of hospital discharge to complete the course of therapy.[129]

For arthritis, a 1-month course of oral doxycycline or amoxicillin is recommended, with a repeat course of oral therapy if inflammation does not resolve.[129] For patients with moderate-to-severe joint swelling after a 1-month course of oral antibiotics, intravenous ceftriaxone for 2 to 4 weeks can be used.[133] Longer courses of antibiotics for unresolved inflammation provide no additional benefit.[104] In this

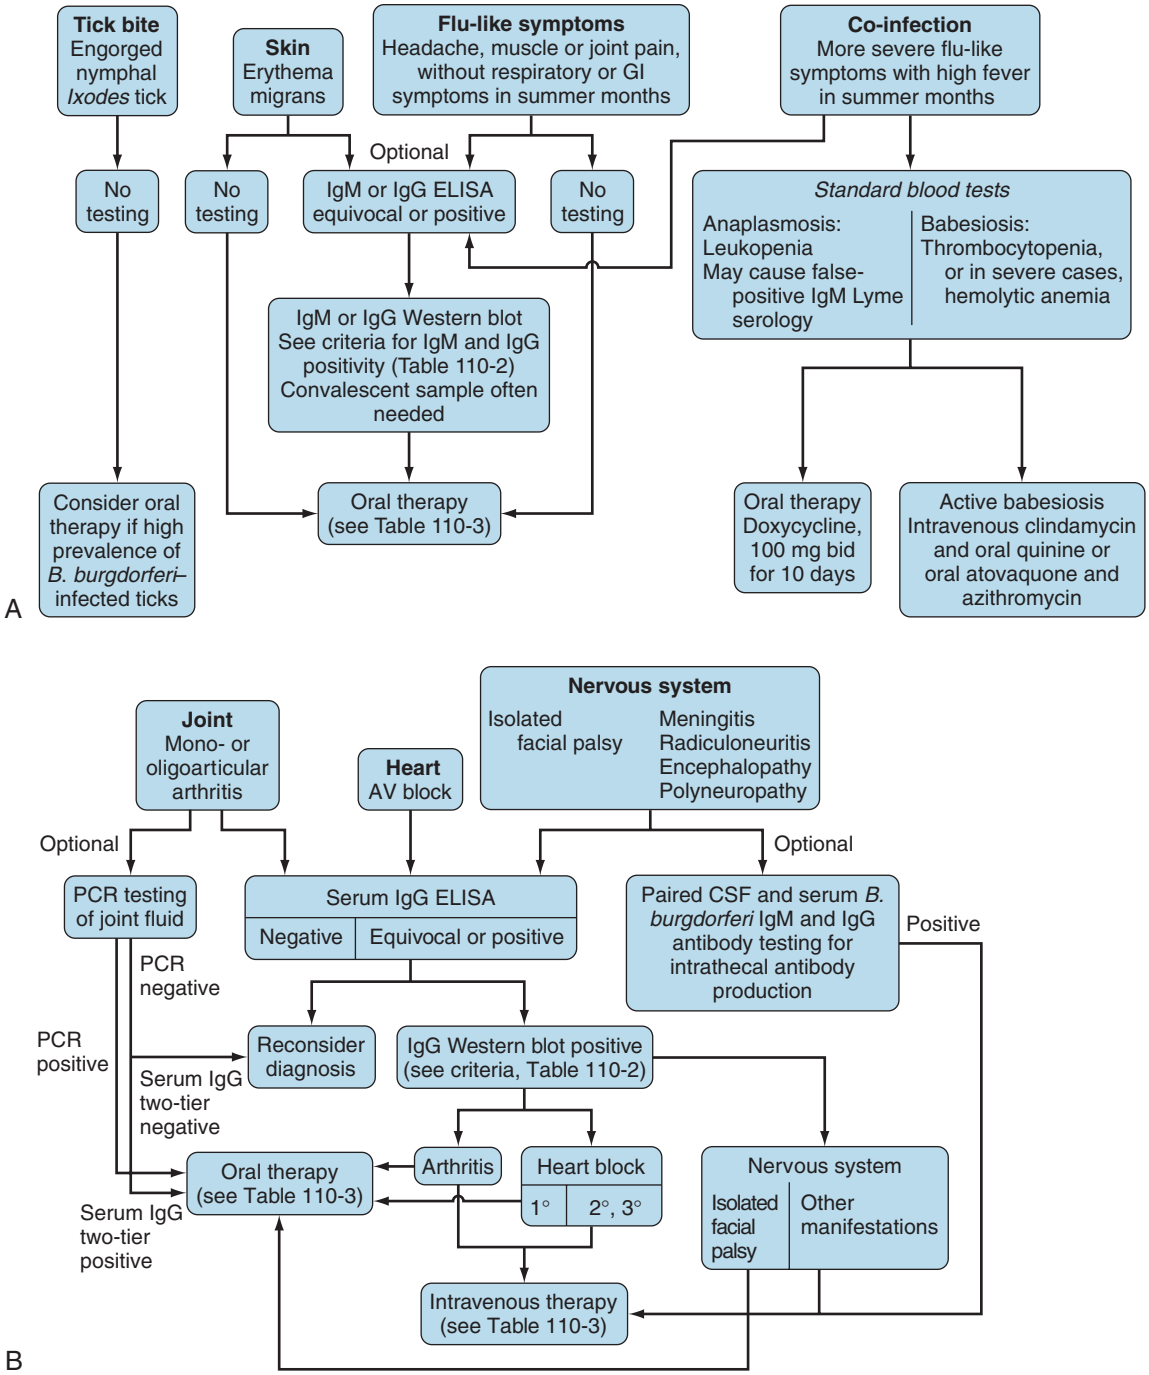

**Figure 110-3** Algorithms for diagnosis and treatment of Lyme disease for people living in or with recent (≤1 month) travel to endemic areas. **A,** Algorithm for evaluation and management of early Lyme disease. **B,** Algorithm for evaluation and management of later organ involvement in Lyme disease. AV, Atrioventricular; ELISA, enzyme-linked immunosorbent assay; GI, gastrointestinal; PCR, polymerase chain reaction. *(From Steere AC, Coburn J, Glickstein L. The emergence of Lyme disease.* J Clin Invest *113:1093–1101, 2014.)*

situation, NSAIDs and hydroxychloroquine are recommended for treatment of antibiotic-refractory Lyme arthritis. In rare patients who do not respond to this approach, other disease-modifying anti-rheumatic drugs such as methotrexate and TNF inhibitors have been used with success. Arthroscopic synovectomy is curative in two-thirds of patients who do not respond to medical management.[134] Intra-articular corticosteroids may be associated with a higher rate of antibiotic unresponsiveness if instituted before antibiotic therapy. Use of intra-articular steroids once antibiotic therapy has commenced can accelerate resolution of inflammation and reduce the incidence of antibiotic-refractory arthritis in children.[135]

## Pregnancy and Lyme Disease

Pregnant and lactating women with Lyme disease can be treated with the same antibiotic regimens recommended for non-pregnant patients except that doxycycline should be avoided.[129] Maternal-fetal transmission of *B. burgdorferi*

**TABLE 110-3** Recommended Treatment of Lyme Disease*

| Manifestation | Drug | Adult Dosage | Pediatric Dosage | Duration (Range) |
|---|---|---|---|---|
| Erythema migrans (recommended) | Doxycycline† | 100 mg orally twice a day | <8 yr—not recommended<br>≥8 yr—4 mg/kg/day in 2 divided doses (max 100 mg/dose) | 14 days (10-21 days) |
| | Amoxicillin | 500 mg orally three times a day | 50 mg/kg/day in 3 divided doses (max 500 mg/dose) | 14 days (14-21 days) |
| | Cefuroxime axetil | 500 mg orally twice a day | 30 mg/kg/day in 2 divided doses (max 500 mg/dose) | 14 days (14-21 days) |
| Erythema migrans (alternative)‡ | Azithromycin | 500 mg orally daily | 10 mg/kg qd (max 500 mg/day) | 7-10 days |
| | Clarithromycin | 500 mg orally twice a day (if patient is non-pregnant) | 7.5 mg/kg bid (max 500 mg/dose) | 14-21 days |
| | Erythromycin | 500 mg orally four times a day | 12.5 mg/kg qid (max 500 mg/dose) | 14-21 days |
| **Acute Neurologic Disease** | | | | |
| Cranial nerve palsy§ | Same as oral regimens for erythema migrans | | | 14 days (14-21 days) |
| Meningitis or radiculopathy‖ | Ceftriaxone | 2 g IV daily | 50-75 mg/kg IV daily in single dose (max 2 g/day) | 14 days (10-28 days) |
| (Alternative IV) | Cefotaxime | 2 g IV every 8 hrs | 150-200 mg/kg/day IV in 3-4 divided doses (max, 6 g/day) | 14 days (10-28 days) |
| | Penicillin G | 18-24 million U/day, divided every 4 hrs | 200,000-400,000 U/kg/day divided every 4 hr (max 18-24 million U/day) | 14 days (10-28 days) |
| Cardiac disease¶ | Same as for erythema migrans *OR* | | | 14 days (14-21 days) |
| | IV regimen as for neurologic disease | | | 14 days (14-21 days) |
| **Late Disease** | | | | |
| Arthritis without neurologic involvement | Same as erythema migrans | | | 28 days (28 days) |
| Recurrent arthritis after oral regimen | Repeat oral regimen *OR*<br>IV regimen as neurologic disease | | | 14 days (14-28 days) |
| Central or peripheral nervous system disease | IV regimen as acute neurologic disease | | | 14 days (14-28 days) |

*Complete response to treatment may be delayed beyond the treatment period, regardless of the clinical manifestation, and relapse may recur. Patients with objective signs of relapse may need a second course of treatment.

†Tetracyclines are relatively contraindicated in pregnant or lactating women and in children younger than 8 years.

‡Due to their lower efficacy, macrolides are reserved for patients who are unable to take or who are intolerant of tetracyclines, penicillins, and cephalosporins.

§Patients without clinical evidence of meningitis may be treated with an oral regimen. The recommendation is based on experience with seventh cranial nerve palsy. Whether oral therapy would be as effective for patients with other cranial neuropathies is unknown; the decision between oral and parenteral therapy should be individualized.

‖For non-pregnant adult patients intolerant of β-lactam agents, doxycycline 200-400 mg/day orally (or IV if unable to take oral medications) in 2 divided doses may be adequate. For children aged 8 years and older, the dosage of doxycycline for this indication is 4-8 mg/kg/day in 2 divided doses (maximum daily dosage of 200-400 mg).

¶A parenteral antibiotic regimen is recommended at the start of therapy for patients who have been hospitalized for cardiac monitoring; an oral regimen may be substituted to complete a course of therapy or to treat outpatients. A temporary pacemaker may be required for patients with advanced heart block.

does occur,[136] but in contrast to syphilis in pregnancy, there is no evidence that the organism causes a congenital syndrome.[137,138] Pregnant patients should be reassured that with recommended therapy for Lyme disease, *B. burgdorferi* infection in the mother should not cause harm to the fetus.[138]

## OUTCOME

Most patients treated for Lyme disease with recommended courses of antibiotics resolve the disease.[139,140] Some patients may experience a Jarisch-Herxheimer reaction, a self-limited worsening of symptoms within 24 to 48 hours of initiation of antibiotic therapy.[141] Within the first week of treatment, patients may rarely show evolution of disease, such as the development of new EM lesions or facial nerve palsy, but these signs should improve while therapy progresses. Most patients with Lyme arthritis experience resolution of joint inflammation after a 1-month course of oral antibiotics, and less than 10% of patients progress to antibiotic-refractory arthritis.[104] Two recent reports from Europe evaluated the short-term (6 months) and long-term (median, 5 years) outcomes of children who had Lyme neuroborreliosis.[142,143] Overall, complete clinical resolution was seen in the majority during the long term, although mild residual deficits occurred in some (incompletely resolved facial palsy or mild motor or sensory deficits). Importantly, nonspecific symptoms, such as fatigue, headache, and cognitive issues, were no more frequent in patients who had a

history of neuroborreliosis than in age-matched controls, and residual deficits did not affect school performance.

Subjective complaints of fatigue and musculoskeletal pain may persist for months after treatment for Lyme disease.[144] Objective, nonprogressive signs are likely to be the result of irreversible tissue damage, and further antibiotic therapy does not seem to be beneficial.[145-148] When patients complain of persistent pain and fatigue, evaluation for coinfection with *B. microti* or *A. phagocytophilum* should be performed.[149] Patients with coinfection tend to be more symptomatic at presentation and can have a delayed resolution of symptoms compared with patients with Lyme disease alone. The impact of coinfection with the newly emergent *Ixodes* tick-borne relapsing fever spirochete *Borrelia miyamotoi* on Lyme disease is not yet known.[150,151]

## Chronic Lyme Disease and Post–Lyme Disease Syndrome

There is a great deal of controversy over the potential for Lyme disease to cause life-altering chronic morbidity in patients. It is unusual to have objective signs after recommended antibiotic regimens for Lyme disease diagnosed according to the guidelines discussed earlier, and when such signs (e.g., Lyme arthritis) are present, further antibiotic therapy does not alter outcome.[139] Recurrent EM after treatment for an initial episode of Lyme disease is caused by reinfection rather than resurgence of the original infection.[152] Even when objective signs are present, they are usually nonprogressive (e.g., residual facial weakness after facial palsy) or resolve with time (as is the case for Lyme arthritis). Use of the term *chronic Lyme disease*, which implies ongoing infection, for nonprogressive signs and symptoms after Lyme disease is not valid.

A few patients treated for Lyme disease may have fatigue, musculoskeletal pain, and complaints of memory impairment despite conventional or prolonged courses of antibiotic therapy, a condition referred to as *post–Lyme disease syndrome*.[145,153] In several controlled, population-based cohort studies that used validated standardized measures of outcomes (e.g., Short Form-36), patients with Lyme disease had more joint pain, symptoms of memory impairment, and worse functional status because of pain compared with controls.[154-156] These complaints could not be documented by abnormalities on physical examination or by neurocognitive testing, however, and a follow-up study showed that quality-of-life measures improved with time.[157] Psychological factors and the presence of psychiatric comorbidity in patients with Lyme disease correlate with poor functional outcomes after treatment.[158] A European study demonstrated that the frequency of nonspecific symptoms at 6 and 12 months after treatment for early Lyme disease was no greater than that of the control group, which included family members without a history of Lyme disease.[159,160] Children are less likely than adults to have persistent complaints after treatment for Lyme disease.[156]

Two randomized, double-blind, placebo-controlled trials of antibiotic therapy were conducted on seropositive and seronegative patients with chronic symptoms (>6 months) after treatment for Lyme disease.[146] Patients were randomly assigned to receive either intravenous ceftriaxone for 1 month followed by 2 months of oral doxycycline or matched intravenous and oral placebos. An interim analysis resulted in termination of the study because no differences in outcome between groups receiving antibiotics or placebo were found, and evidence of ongoing infection could not be documented. Another trial of antibiotics for post-treatment Lyme disease symptoms found that fatigue improved in the group receiving intravenous ceftriaxone, but cognitive dysfunction did not.[147] Individuals who had positive IgG immunoblots for Lyme disease and who had not received prior treatment with intravenous antibiotics were more likely to have improvement in fatigue. Subsequently, a randomized, placebo-controlled trial of a 10-week course of intravenous ceftriaxone for memory impairment after treatment for Lyme disease did not show sustained improvement in cognitive function.[148] An open pilot study provided evidence that gabapentin may be effective in the treatment of chronic pain syndromes after Lyme disease.[161]

A growing number of patients with similar subjective complaints are being treated for months or years with antibiotics for presumed *B. burgdorferi* infection.[162-164] These patients are diagnosed with *chronic Lyme disease* even though they often have no serologic evidence of *B. burgdorferi* exposure or are considered as testing positive on the basis of IgM reactivity on immunoblot despite years of not feeling well. They typically experience only partial resolution of their symptoms with antibiotics. Occasionally, patients may have other conditions such as rheumatoid arthritis or fibromyalgia, for which therapy has been delayed because of a misdiagnosis of Lyme disease.[164] Musculoskeletal pain is common in the general population; 20% to 30% of adults complain of chronic fatigue.[165] In the absence of a clinical history with objective manifestations of Lyme disease or positive two-tiered serologic tests, definitive attribution of symptoms to *B. burgdorferi* infection cannot be made. Caution should be exercised when attributing symptomatic response to the anti-microbial effects of antibiotics. Ceftriaxone and other β-lactam antibiotics can modulate neurotransmitter activity,[166] and tetracyclines inhibit matrix metalloproteinases.[167,168] Prolonged antibiotic use is not without risk. Minor side effects are common, and serious adverse events such as biliary complications from ceftriaxone therapy or indwelling catheter–related infections occur at high enough rates to warrant only judicious use of antibiotics.[146,148,162]

# PREVENTION

The most effective way to prevent Lyme disease is to reduce exposure risk to *B. burgdorferi*–infected ticks through personal protective measures and environmental controls.[169] These measures include avoidance of tick habitats such as wooded areas, stone fences, woodpiles, and tall grass, wearing protective clothing, and performing daily surveillance and prompt removal of ticks (within 24 hours of feeding). Other effective measures include use of DEET-containing insecticide sprays, yearly application of acaricides to property to kill ticks, construction of four-poster bait stations that apply acaricides onto deer as they feed, and tall fences to prevent deer from incidentally transporting ticks to an area.

A single 200 mg dose of doxycycline (or 4 mg/kg to as much as 200 mg for children aged 8 years and older) reduces the incidence of Lyme disease after a recognized tick bite[170]

but is not routinely recommended because of the low rate of infection.[129] An FDA-approved recombinant Osp A–based vaccine to prevent Lyme disease was withdrawn because of low market demand and concern for potential vaccine-related side effects.[171,172]

## CONCLUSION

Lyme disease is a localized or systemic infection that usually manifests with skin and musculoskeletal signs and symptoms, but it can involve other organ systems, especially the nervous system and more rarely the heart. The diagnosis should be based on objective clinical findings consistent with Lyme disease and supporting serologic tests. Most patients are cured with 2 to 4 weeks of antibiotic therapy, although the time to disease resolution may be prolonged, especially for individuals in whom therapy was delayed; irreversible tissue damage may occur. A poor response to antibiotic therapy should raise concern for alternative diagnoses or coinfection with other tick-borne pathogens. Arthritis becomes refractory to antibiotics in less than 10% of patients with Lyme arthritis. Treatment with NSAIDs, hydroxychloroquine, or other disease-modifying anti-rheumatic therapies usually resolve arthritis within 4 to 5 years. Some patients treated for Lyme disease experience a post–Lyme disease syndrome of fatigue, headaches, mild memory impairment, and musculoskeletal pain. Ongoing infection cannot be shown, and controlled treatment trials show no benefit of prolonged antibiotic therapy over placebo. Referral to an academic medical center with experience in the diagnosis and treatment of Lyme disease should be considered when patients do not respond as expected to therapy.

CHAPTER 111

# Mycobacterial Infections of Bones and Joints

Eric M. Ruderman • John P. Flaherty

**KEY POINTS**

- Global rates of tuberculosis disease have declined in recent years because of improvements in case detection and expansion of treatment, but resistance to anti-tuberculous drugs remains a threat. Rheumatologists must remain vigilant for tuberculosis disease in an era of expanded use of TNF inhibitors and other biologic agents.
- Musculoskeletal tuberculosis typically is seen as a chronic localized infection, most commonly involving the spine, less often the hip or knee.
- Diagnosis can be very difficult and often requires biopsy for histopathology and culture of the bone or synovium; rapid diagnostic test techniques are revolutionizing the early detection of pulmonary tuberculosis and, although promising, have not yet proved reliable in bone and joint specimens.
- The tuberculin skin test (TST) can be helpful in identifying latent tuberculosis before treatment with TNF inhibitors, but it is limited by false-positive and false-negative results. IFN-γ release assays might be as sensitive as and even more specific than TSTs, but they are expensive and associated with false-positive and false-negative test results.
- Treatment requires multiple agents selected on the basis of susceptibility testing for 6 to 9 months and has been complicated by drug resistance.
- Nontuberculous mycobacteria are important pathogens to recognize in the face of biologic therapy for rheumatic diseases.

The recognition of tuberculosis (TB) and other mycobacterial infections of the musculoskeletal system has become a major challenge for rheumatologists in the United States and other developed countries. Before 1999, most rheumatologists could easily go an entire year without seeing a single case of mycobacterial infection. Such cases were rare even at academic centers, where they would likely be presented as unusual teaching cases at clinical conferences.

However, 1999 introduced the routine clinical use of TNF inhibitor therapy in the United States, and with it came an unexpected increase in TB cases seen by rheumatologists. Fortunately, the initiation of routine screening with tuberculin skin test (TSTs) and interferon gamma release assays (IGRAs) has led to a sharp decline in the number of new cases, particularly those associated with reactivation of latent infection. However, the risk of primary infection with new exposure mandates continued vigilance in these patients and potentially those on other biologic therapies. Moreover, for non-TB mycobacterial infections, there are no screening tests available, making vigilance on immunosuppressive therapy even more important.

Another major force driving the increase in mycobacterial infections is the ongoing HIV epidemic. In the pre-highly active anti-retroviral therapy era, 21% of extrapulmonary TB cases in the United States were associated with underlying HIV infection. In developing countries, the HIV pandemic has led to marked increases in osteoarticular TB coinfection.[1] These cases are distinguished by disseminated multifocal disease suggestive of hematogenous spread, rapid progression, and more common coexistence with pulmonary infection.[2,3] HIV testing should be a routine part of the workup of any patient presenting with a musculoskeletal infection secondary to *Mycobacterium tuberculosis*. The good news is that since the introduction of effective anti-retroviral therapy, the incidence of TB and nontuberculous mycobacterial infection in patients co-infected with HIV has declined sharply in the United States.

TB is an uncommon disease in the developed world. In the United States, the incidence of TB has been steadily declining since 1990, and the majority of TB cases now may be considered imported (i.e., occurring in foreign-born individuals).[4] Worldwide, TB remains one of the world's deadliest infectious diseases.[4,5] In 2013, an estimated 9 million people developed TB, and 1.5 million people died of the disease. Worldwide, it is the number two infectious disease killer after HIV. Someone in the world is newly infected with TB bacilli every second. Approximately one-third of the world's population is infected with TB, providing a reservoir that will continue to complicate its global control.[6] More alarming are increasing rates of multidrug resistant TB (MDR-TB) and emergence of extensively drug-resistant TB (XDR-TB).[7] These strains fail to respond to all first-line and most second-line TB agents. Globalization of the world economy promotes contact between populations of the developed and developing worlds. Immigrants to the United States from areas endemic for TB constitute an ongoing reservoir of patients with latent TB.

The challenge of diagnosing musculoskeletal mycobacterial infection reaches beyond the rarity of the disease. Such infections are often indolent and may lack the pain, fevers, chills, and other prominent symptoms that typically accompany bacterial infections of the musculoskeletal system. In addition, routine culture techniques will not isolate the organism, so unless the diagnosis of TB is a consideration from the outset, the diagnosis may be missed. Delayed diagnosis of mycobacterial infections of the musculoskeletal system is common and will remain without a heightened index of suspicion for these types of infections.

For all these reasons, 21st century rheumatologists need to be well informed about a group of diseases with which they may have had limited experience.

## CLINICAL SCENARIOS

To appreciate the entire spectrum of clinical problems a rheumatologist may encounter in dealing with mycobacterial infections, it is useful to think in terms of several distinct categories. Franco-Paredes[8] and colleagues provide a clinically useful division of mycobacterial infections into four major categories. The following sections reflect that division.

### Direct Involvement of the Musculoskeletal System

Musculoskeletal infections caused by mycobacteria typically present as chronic, indolent, localized involvement of the bones, spine, peripheral joints, or soft tissues that produces a focus of nonspecific pain and, less often, swelling. In infections initiated by direct tissue inoculation, the traumatic event is often trivial or remote in time from the onset of clinical disease. Diagnosis may be delayed for months to years, in part because of minimal early symptoms and attribution of those symptoms to a noninfectious disorder until disease progression and disability prompt a more aggressive diagnostic investigation.

Constitutional symptoms are typically subtle or absent, and laboratory indicators of inflammation are often normal. Synovial effusion is frequently minimal, and the fluid, if it is obtainable, shows nonspecific inflammation. Radiographic abnormalities may be delayed, although newer imaging techniques have allowed the earlier detection of abnormalities and the distinction of TB from other infections and neoplasm.[9,10] Characteristic pulmonary or extrapulmonary findings are not always present; for example, less than 50% of osteoarticular TB presents with evidence of active or past pulmonary disease. TSTs and IGRA testing may provide useful clues to the cause, but results are not invariably positive, especially in debilitated or immunosuppressed patients. Correct diagnosis is highly dependent, in most cases, on demonstration of the infectious agent by microscopic examination and culture of affected tissue.

In HIV-infected patients, mycobacterial infections are often diagnosed before the patients' $HIV^+$ status is known, sometimes leading to its recognition.[11] Atypical pulmonary TB and extrapulmonary (often multifocal) infection are common; extrapulmonary infection occurs in 60% to 70% of such cases, compared with 16% of all patients with TB.

The clinical patterns of musculoskeletal TB include spondylitis, osteomyelitis, peripheral joint infection, and soft-tissue abscess. In a series of 230 consecutive cases of TB from the pre-antibiotic era, 5.2% had skeletal involvement; the spine was affected in 60% of these cases.[12] TB of the bones and joints is spread hematogenously. The sites most commonly affected are the spine and hips, followed by the knees and wrists; other joint involvement is rare. Constitutional symptoms are unusual in musculoskeletal TB and, when present, suggest TB in other organs. Vertebral collapse because of spinal TB may initially be attributed to the more common osteoporosis-caused spinal compression fracture.

| Other debilitating diseases |

TB only rarely involves skeletal muscle but must be considered in the differential diagnosis of an enlarging muscle lesion.[13-17] Isolated cases involving tendons, trochanteric bursa, and fascia lata illustrate the variety of possibilities.[18-21] Biopsy and culture are required for diagnosis. Imaging studies do not reliably distinguish TB from neoplasm.

In nonendemic areas, skeletal TB usually occurs in elderly, debilitated patients, most often in the form of solitary osteolytic lesions in the axial skeleton. The development of skeletal disease is often remote from the initial infection, which strongly implies reactivation of previous subclinical disease. Patients may have false-negative TSTs for several reasons, including long-term corticosteroid use or coexisting debilitating diseases, such as rheumatoid arthritis (RA) or chronic renal failure, that compromise resistance and produce anergy (Table 111-1).[22,23] The occurrence of spinal disease in children in nonendemic regions has mostly been eliminated by effective medical therapy of pulmonary infection.

In contrast, in endemic areas with high infectivity rates, those infected are more commonly children and young to middle-aged adults. These individuals have a higher incidence of multifocal skeletal involvement in the ribs, pelvis, vertebrae, feet, and long-bone diaphyses.[24] Bone seeding occurs through hematogenous spread, sometimes secondarily from another extrapulmonary site. When pulmonary findings are present, a miliary pattern is typical. Spread to bone may also occur from infected nodes, either by direct extension or through draining lymph channels.[25]

#### Spondylitis

The spine is the dominant site of involvement in skeletal TB, accounting for 50% to 60% of cases.[26] Between 48% and 67% of lesions occur in the lower thoracic and thoracolumbar spine in $HIV^-$ patients, whereas the lumbar spine is most commonly involved in $HIV^+$ patients.[3] Infection usually begins in the anterior subchondral bone of a single vertebra adjacent to the intervertebral disk (Figure 111-1 and Figure111-2). Progression occurs during 2 to 5 months and begins with extension from cancellous to cortical bone, and then across the disk space to adjacent vertebrae (Figure 111-3). Bone destruction may lead to vertebral collapse, which typically occurs anteriorly, resulting in gibbous deformity. Isolated neural arch involvement and intraspinal abscess may also occur.

Paravertebral abscess begins with the extension of infection under the anterior longitudinal ligament. In the

thoracic spine, this may extend into the pleural space and lung parenchyma. In the cervical region, it may spread to the posterior cervical triangle or retropharyngeal space. In the lumbar spine, a cold abscess characteristically produces lateral displacement of the psoas muscle and may dissect along its length to present as a mass in the inguinal triangle, gluteal muscle, or upper thigh. In isolated cases, a cold abscess occurs without apparent bone involvement.

A particular variant of this presentation is subligamentous TB, in which infection spreads up and down the spine beneath the longitudinal ligament, producing scalloping of multiple anterior vertebral bodies without disk involvement. This pattern is more common in the cervical spine.[27]

The clinical presentation of spinal TB usually consists of localized pain, which may be accompanied by low-grade fever, weight loss, chills, and nonspecific constitutional symptoms. Paraparesis and paraplegia have been reported in 1% to 27% of patients in various series. In comparison with pyogenic vertebral osteomyelitis, patients with spinal TB more often are seen with a prolonged clinical course, thoracic segment involvement, spinal deformity, neurologic deficit, and paravertebral or epidural masses, and more often without fever, chills, and constitutional symptoms.[27] On occasion, patients with tuberculous spondylitis are seen with chronic inflammatory-type back pain more typical of a spondyloarthropathy.[28]

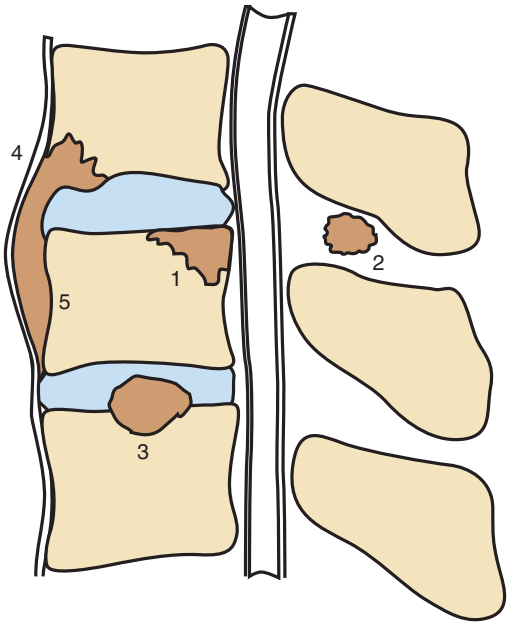

**Figure 111-1** Tuberculous spondylitis: sites of involvement. Tuberculous lesions can localize in the vertebral body *(1)* or, more rarely, in posterior osseous or ligamentous structures *(2)*. Extension to the intervertebral disk *(3)* or pre-vertebral tissues *(4)* is not infrequent; subligamentous spread *(5)* can lead to erosion of the anterior vertebral surface. *(From Resnick D:* Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2464.)*

**Figure 111-3** Tuberculous spondylitis with spinal cord compression. MRI of the lumbar spine shows destruction of contiguous vertebral bodies and an inflammatory mass pressing on the spinal cord. This patient was successfully treated with medical therapy alone.

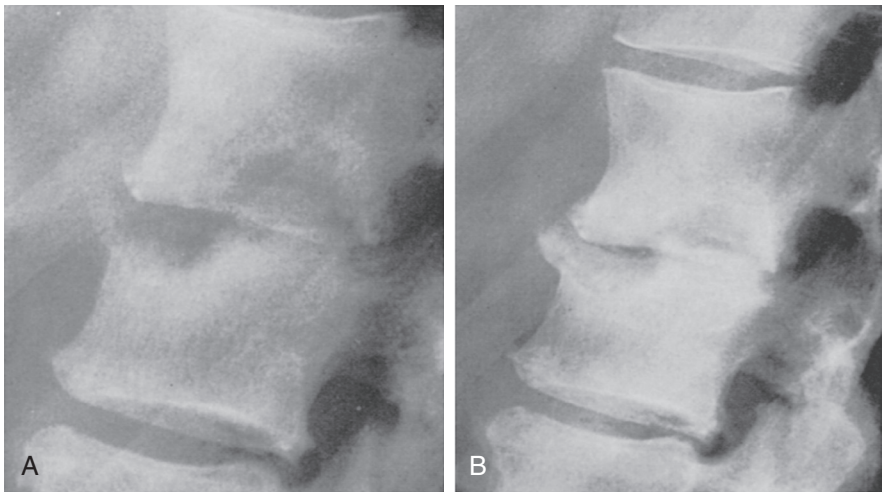

**Figure 111-2** Tuberculous spondylitis with discovertebral lesion. **A,** The initial radiograph reveals subchondral destruction of two vertebral bodies, with mild surrounding eburnation and loss of intervertebral disk height. The appearance is identical to that in pyogenic spondylitis. **B,** Several months later, an osseous response is evident. Note the increased sclerosis. Osteophytosis and improved definition of the osseous margins can be seen. *(From Resnick D:* Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2465.)*

Mycobacterial colony counts in bone biopsy specimens are relatively low. Only 40% of smears and cultures from psoas abscesses are positive. Among patients meeting strict clinical and radiographic criteria in one series, between 73% and 82% had compatible histologic features on biopsy; of these, 80% to 95% had positive culture results.[25] The differential diagnosis, which is extensive, includes pyogenic and fungal osteomyelitis, primary and metastatic tumors, sarcoidosis, multiple myeloma, and eosinophilic granuloma.

Cervical spine involvement is relatively rare, accounting for only 0.4% to 1.2% of cases of extrapulmonary TB in the United States.[29] The most common presenting symptoms are neck pain and stiffness, although hoarseness, dysphagia, torticollis, fever, anorexia, and neurologic disorders may also occur. Spinal involvement can progress to myelopathy because of delays in diagnosis. Radiographs may show characteristic osteolysis of the anterior vertebral body with sparing of the posterior portion, gibbus deformity, disk involvement, and a partially calcified paraspinous mass. CT or MRI is useful for assessing compromise of the spinal canal. Retropharyngeal infection may extend into the craniocervical junction and, if not promptly recognized, may cause atlantoaxial dislocation and neurologic complications.[30,31]

The sacroiliac joint is involved in as many as 10% of cases of skeletal TB, often without other evidence of disease.[32] Infection, and TB in particular, should be considered in all cases of unilateral sacroiliitis, particularly when other features of a spondyloarthropathy are absent. Emigration from an endemic area and a past history of TB increase the likelihood of this cause. Buttock pain on the involved side is the patient's presenting symptom and is often accompanied by proximal leg or radicular pain. Examination reveals sacroiliac tenderness to palpation and stress maneuvers. Sacroiliac films show joint widening and erosion. An elevated erythrocyte sedimentation rate (ESR) and anemia are common, and a positive tuberculin reaction is typical. Biopsy of the sacroiliac joint shows granulomatous histologic features or nonspecific inflammation and a positive culture in most cases.

Atypical spinal lesions, which occur in approximately 10% of cases, may lead to delayed diagnosis and treatment. Atypical radiographic presentations in a single vertebra include concentric collapse, sclerotic foci, and selective involvement of the vertebral arches and costotransverse joints. Multiple vertebrae may be involved, either in continuity or as skipped lesions. Atypical clinical presentations may suggest a herniated intervertebral disk, failed back syndrome, spinal tumor, or a meningeal granuloma.[26,33]

### Tuberculous Osteomyelitis

Bone lesions begin with hematogenous implantation of organisms in the medullary area. Metaphyseal involvement is most common, and lesions may spread through the growth plate to involve the adjacent joint, usually late in the disease course. Lesions are typically destructive. Lytic lesions in unusual areas, such as the pubic symphysis, sacroiliac joint, and elbow, can be misdiagnosed as malignancy.[34] Osteomyelitis may occur in a bone or joint that has been previously exposed to trauma.

Tuberculous osteomyelitis occurs in both children and adults.[35] Although any bone can be involved, the femur and tibia are most commonly affected. Dactylitis may also occur in children. In one large series from an endemic area, such cases represented 19% of bone and joint TB and 15% of cases of osteomyelitis of hematogenous origin.[36] Bone pain was the most common presentation; a draining sinus, abscess formation, and local swelling and tenderness were also common. The average delay before diagnosis was 28 months.

Multifocal osteoarticular TB is a less common variant of the disease,[36,37] but TB should be considered in all patients from endemic areas who are seen with multiple destructive skeletal lesions.

For a definitive diagnosis of osteoarticular TB, a biopsy specimen of an affected site must be obtained.[19] Soft-tissue lesions characteristically demonstrate rim enhancement on CT examination. CT may also facilitate percutaneous needle biopsy or abscess drainage.[38] Histologic examination generally reveals granulomatous inflammation. In one series of 121 cases, biopsy showed a positive culture in 33%, granulomatous histologic features in 46%, and both in 21%.[39] Radiographic findings include cavity formation with a thin adjacent layer of sclerosis in about 50% of cases, sometimes containing a sequestrum. The true extent of bone involvement may be difficult to detect because of clinically silent lesions. Bone imaging with technetium 99, although more sensitive than conventional radiographs, may provide false-negative results in early, indolent, or highly destructive disease. Tuberculin test reactions are positive in more than 80% of cases.[40]

Treatment with anti-tuberculous therapy is generally effective. In a minority of cases, surgical debridement is required for healing. Initiation of therapy on the basis of histologic findings is appropriate pending culture results. Sinus cultures are commonly positive for pyogenic bacteria both before and after anti-tuberculous therapy, but these are presumed to be contaminants. Healing is associated with sclerosis at the margin of lesions. Misdiagnosis of the condition as pyogenic osteomyelitis may lead to unnecessary surgery or to delayed anti-tuberculous treatment, resulting in extension of infection into the joint and chronic disability.

### Septic Arthritis

The typical pattern of tuberculous joint involvement is a monoarticular arthritis involving the large joints, most commonly the hip and knee (Figure 111-4 and Figure 111-5).[41,42] Other joints less commonly involved include the sacroiliac, shoulder, elbow, ankle, carpal, and tarsal joints. Infection begins in the synovium, with progression of destructive changes being slower than in pyogenic septic arthritis. Prosthetic joint infection with M. *tuberculosis* has been reported, and is usually caused by local reactivation of latent disease.[43]

The diagnosis of tuberculous arthritis is often missed. A consecutive series spanning the years 1970 to 1984 emphasized typical features.[44] Of 23 cases of musculoskeletal TB, 9 involved the spine, 1 the hip, and the remaining 13 the peripheral joints. Most patients were men older than 50 years. The history of TB or exposure was generally

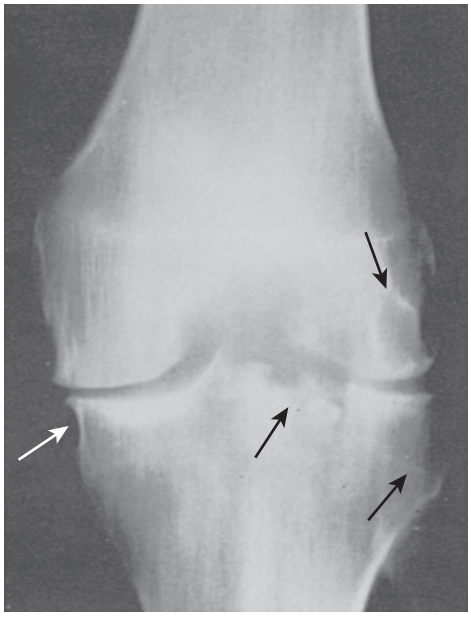

**Figure 111-4** Tuberculous arthritis of the knee. On conventional computed tomography, typical marginal and central osseous erosions *(arrows)* accompany tuberculous arthritis. Osteoporosis is not prominent. *(From Resnick D:* Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2480.)*

**Figure 111-5** Tuberculous arthritis following total hip replacement. A sinus tract emerges from the scar following total hip arthroplasty for childhood destructive arthritis of unknown cause. The young man was originally from Vietnam.

forgotten. In all cases, presenting symptoms were joint pain and swelling. Four patients had evidence of active pulmonary TB, and in two patients with sterile pyuria, M. *tuberculosis* grew from the urine. Only 5 of 10 patients tested had a positive TST. Radiographs showed changes of erosive arthritis in 7 and no changes in 4 of 11 joints studied. The median delay in diagnosis was 8 months.

Arriving at a correct diagnosis requires vigorous pursuit and usually a synovial biopsy and culture. Initial studies are often misleading and may contribute to delayed diagnosis or misdiagnosis. Synovial fluid findings are variable and do not distinguish this arthropathy from other inflammatory or septic arthritides.[45] Cell counts more often suggest bland inflammatory, rather than septic, arthritis and may contain a preponderance of neutrophils. The diagnosis may be facilitated if the organism is observed on an acid-fast smear of synovial fluid, but only 10% to 20% of reported cases are positive. In contrast, synovial fluid cultures are frequently positive. Radiographic changes are similar to those seen in other septic arthritides, beginning with juxta-articular bone demineralization and progressing to marginal bone erosion and articular cartilage destruction (see Figure 111-4).

With the open-biopsy technique, granulomatous histologic features and positive cultures are present in more than 90% of cases.[45] Experience with direct amplification tests in mycobacterial arthritis is limited and suggests that they have limited sensitivity but good specificity (63% and 100% in one small case series.[46] The histologic examination alone may be confusing, because granulomatous synovitis can also be found in nontuberculous mycobacterial infection, sarcoidosis, erythema nodosum, brucellosis, Crohn's disease, and foreign-body reaction. As noted, synovial acid-fast smear is of limited value. Tuberculous arthritis is also reported in children, sometimes early in the disease course; synovial biopsy and culture are recommended in children with monarthritis and a TST or IGRA.[47]

TB must be considered among the possible causes of septic arthritis occurring in patients with pre-existing RA, although it is not widely seen in developed countries.[48,49] Conversely, rheumatoid factor may be present in TB, leading to diagnostic confusion in the presence of chronic monarthritis.[48]

## Emergence of Tuberculosis During the Treatment of Rheumatic Diseases

Many patients with systemic rheumatic disease have dysregulated immune systems that are treated with immunosuppressive drugs. Such an impaired immune response may permit the reactivation of latent TB. TNF plays a key role in granuloma formation and stabilization, which promotes the containment of M. *tuberculosis*. The rate of TB among patients with RA before the widespread use of TNF inhibitors was approximately 6 cases per 100,000,[50] although some studies have suggested that the rate in RA is higher than in the general population.[51] In one large patient registry, the estimated incidence of TB associated with infliximab in RA patients was in excess of 1000 per 100,000 person-years of exposure during the years 2000 to 2001.[52] In the United States, the rate was 52 per 100,000 person-years during the same time period.[50] Etanercept may be associated with a lower risk for TB reactivation than infliximab: 10 cases per 100,000 person-years of exposure with etanercept, versus 41 per 100,000 person-years with infliximab, according to an analysis of Food and Drug Administration data.[53] Similarly, British and French registries have identified a greater risk for TB associated with the use of adalimumab and infliximab than with etanercept.[54,55] There are fewer data available for the newer TNF antagonists, and comparisons are

complicated by the widespread use of pre-treatment screening instituted after the first agents in this class were approved for use. Monoclonal antibodies to TNF may play a greater role in destabilizing granulomas than soluble TNF receptors. Nonetheless, similar precautions should be taken with any TNF antagonist and all should be presumed to increase the risk of both new infection and reactivation of latent infection.

Tocilizumab (which blocks IL-6), golimumab, and certolizumab have been associated with reports of TB disease, but because these cases occurred in TB-endemic countries, infection may have been acquired during treatment. Nevertheless, the labeling for all three agents recommends screening before therapy. Other biologic agents may pose a lower risk for reactivation of TB, because the mechanisms of action are not intimately involved with host defense related to intra-cellular organisms. Animal studies have suggested that abatacept does not impair the ability of mice to respond to M. *tuberculosis*, but this has not been confirmed in humans.[56] Little or no evidence indicates that B cells play a major role in containing TB, and there does not appear to be an increased risk of TB following treatment with rituximab.[57]

Glucocorticoid use also poses a significant hazard for patients with latent TB. Many mechanisms account for this effect, including impairment of cellular immune responses and monocyte chemotaxis and function, including the monocyte's production of TNF. The use of glucocorticoids has been associated with a fivefold increased risk for TB in a case-control study involving a large general practice database in the United Kingdom.[58] The risk appeared to be dose related but was seen even at the physiologic dose of prednisone, 7.5 mg/day. Just as with TNF inhibitors, the risk for TB was greatest early in the course of treatment. In a French study, prednisone at 10 mg/day or more but not lower doses, was associated with an increased risk for TB.[55]

Reactivation of TB in the face of TNF inhibitor therapy typically occurs within 6 months of treatment and often manifests as extrapulmonary disease. Institution of a protocol to screen and treat for latent TB infection (LTBI) in patients with RA before TNF antagonist administration resulted in a 78% decrease in TB disease.[59] Treatment of LTBI can effectively and safely lessen the likelihood of TB disease in patients treated with TNF antagonists. Indeed, it has been suggested that much of the blame for the development of TB disease in this situation can be attributed to incomplete compliance with screening protocols.[60] Conversely, in a report of 84 patients at a single center who were treated with etanercept after demonstrating a positive TST, no cases of TB disease were seen during a mean of 2 years of follow up despite the fact that 78 of 84 patients were prescribed treatment and only 52 completed the prescribed treatment regimen.[61] Although screening for LTBI has reduced the incidence of TB disease, false-negative TSTs and false-negative and indeterminate IGRAs can undermine such good intentions (see Table 111-1).

The approach to a patient with latent TB who needs a TNF inhibitor has not been standardized. Many authorities recommend that patients with positive TSTs or IGRAs and normal chest radiographs who have never been treated for TB receive at least 1 to 2 months of therapy before beginning a TNF inhibitor, if for no other reason than to be certain that they will be able to tolerate the full course of latent TB therapy. Appropriate regimens include 9 months of isoniazid, 4 months of rifampin, or 3 months of directly observed weekly isoniazid plus rifapentine. Patients discovered to have active TB should receive a complete course of standard anti-tuberculous therapy before initiating a TNF inhibitor.

Although TNF inhibitors and steroids are predominant risk factors for TB, all patients with rheumatic disease treated with immunosuppressive therapy that impairs cellular immunity should be considered at risk. This is especially true in the elderly, the malnourished, and immigrants from countries with high endemic rates of TB.

## Rheumatic Disorders Precipitated By the Treatment of Tuberculosis

A variety of rheumatic conditions may be precipitated by the drugs used in the treatment of TB. These include drug-induced lupus caused by isoniazid (INH) and rifampin. As with other cases of drug-induced lupus, they are associated with positive anti-nuclear antibodies and the presence of anti-histone antibodies. Typically, these patients follow a benign course, with resolution of disease after the drug is discontinued.

Arthropathy and tendinopathy have been described with the use of fluoroquinolones, especially ciprofloxacin and levofloxacin. The risk of tendon rupture (usually the Achilles tendon) is greatest in patients older than 50 years and increases with the concomitant use of corticosteroids.

Pyrazinamide interferes with the renal tubular excretion of uric acid and has been associated with the development of hyperuricemia and gout in adults.

Paradoxical reactions have been described in patients withdrawn from infliximab following the diagnosis and initiation of treatment for TB disease.[62] These reactions present as a worsening of pre-existing TB lesions or the development of new lesions not attributable to the normal course of disease in a patient initially improving on treatment. The mechanism for such reactions is not completely understood but has been categorized within the spectrum of immune reconstitution inflammatory syndromes. Such reactions are more common in patients with HIV following the initiation of anti-retroviral therapy. After infliximab therapy is discontinued, its anti-inflammatory effects persist for 3 or 4 weeks which may explain the timing of this delayed reaction. No changes in anti-tuberculous therapy are necessary when a paradoxical reaction occurs; corticosteroids may ameliorate this response.

## Reactive Immunologic Phenomena in the Setting of Tuberculosis

A variety of reactive immunologic phenomena have been associated with M. *tuberculosis* infection. These are uncommonly found in clinical practice.

Poncet's disease is an aseptic inflammatory polyarthritis that occurs in the presence of TB disease. Although any joints can be involved, the most commonly affected are the knees, ankles, and elbows.[63] The mechanism is thought to be similar to other forms of reactive arthritis secondary to remote infection. Most cases resolve after satisfactory

treatment of the TB. Reactive arthritis has been described following the intravesicular instillation of bacille Calmette-Guérin (BCG) vaccine for bladder cancer.[64]

Other seldom-encountered immune reaction patterns described with *M. tuberculosis* include erythema nodosum, erythema induratum, and amyloidosis (AA type).

# DIAGNOSIS

## Tuberculin Skin Test

The TST—also called the *purified protein derivative* (PPD)—has been in use for nearly a century and remains the most widely used screening test for TB. It is routinely administered in rheumatology offices that prescribe TNF inhibitors. The test represents a crude mix of antigens from *M. tuberculosis* and is plagued by both false-positive and false-negative results. It is unable to distinguish latent infection from active disease and may be negative in the face of severe active TB. Corticosteroids (≥15 mg/day of prednisone) may render the TST negative in people with latent TB. Elderly and malnourished patients may not exhibit a positive TST. Table 111-1 provides a partial list of causes for a false-negative TST that are of special interest to rheumatologists.

False-positive results may likewise occur in the case of infection with nontuberculous mycobacteria or previous BCG vaccination. TST positivity degrades with time in BCG-vaccinated patients, at a variable rate. The degree of positivity is influenced by a number of factors, including the number of BCG vaccinations and the number of subsequent TSTs performed. Some patients may retain a response as long as 15 years after BCG vaccination. However, a TST result of 20 mm or greater is rarely the result of BCG. In addition, if faced with a high-risk situation, such as the initiation of TNF inhibitor therapy, one should probably make a presumption of LTBI even if the diameter of induration measures as little as 5 mm.

The important message for rheumatologists is that the TST is an important but imperfect screening tool for latent TB infection, with a sensitivity and specificity in the range of 70%. A negative TST should not eliminate the clinician's vigilance in monitoring patients treated with TNF inhibitors for reactivated or new-onset TB, especially in high-risk populations.

### Interferon-γ Release Assays

The limitations of the traditional PPD skin test in terms of specificity and sensitivity in identifying latent TB have led to the development of new T cell–based testing. These assays measure the production of IFN-γ by whole-blood mononuclear cells stimulated by specific *M. tuberculosis* antigens. The IGRAs, including the Quanti-FERON Gold In-Tube (Cellestis, Inc; Brisbane, Australia) and TSPOT. TB (Oxford Immunotec, Inc; Oxford, England) assays, appear to have equivalent sensitivity and improved specificity when compared with TST.[65,66] These assays contain specific *M. tuberculosis* antigens and are less likely to result in a positive test in people exposed to nontuberculous mycobacteria, including *Mycobacterium avium* complex or the attenuated *Mycobacterium bovis* strain in the BCG vaccine. They also offer the opportunity to circumvent operator error with TST administration and do not require patients to return in 48 to 72 hours to have the test interpreted. IGRAs have replaced the TST in many centers for routine screening for LTBI. Studies of IGRAs in patients with RA and other inflammatory disorders have found them to have comparable or better accuracy than the TST.[67-79]

IGRAs are not without concerns. Indeterminate results from IGRAs in this setting have ranged from 1.2% to 28.6%, raising concerns about the performance of the assay from center to center.[80,81] Within-subject result variability is an issue, especially when the TB antigen response is near the cut-off value.[82,83] Factors that might contribute to IGRA result variability include reagent variability, blood volume, whether the blood tube is shaken gently or vigorously, delays in processing, and PPD-induced boosting of IFN-γ response.[84] Positive IGRAs are more closely related to TB risk factors than are positive TSTs.[85] Discordant $IGRA^-/TST^+$ results are associated with prior BCG vaccination, and discordant $IGRA^+/TST^-$ results are associated with corticosteroid therapy, suggesting that the former represents a false-positive TST and the latter represents a false-negative TST. Nevertheless, the meaning of a discordant result is uncertain enough that patients with a positive test result with either IGRA or TST should be considered for therapy if possible LTBI.[86] Additional experience will be required to provide confidence that a negative IGRA in the setting of a positive TST reliably excludes LTBI. If only one testing modality is utilized, one recent analysis found that use of an IGRA was more cost effective than the TST for patients screened before TNF inhibitor therapy.[87]

IGRAs have also been studied in patients receiving a TNF inhibitor to identify newly acquired TB infection. Many authorities recommend ongoing annual monitoring for new TB infection in patients treated with TNF inhibitors, especially in highly endemic areas. Rates of TST conversion in patients on TNF inhibitor therapy have been reported to be 33% and 37% from centers in Korea and Taiwan; corresponding rates of IGRA conversion were 14% and 11%, respectively, and appeared to better correlate with the risk of active TB.[88,89] Pending formal guidelines, in regions where ongoing exposure to infectious TB may occur, routine monitoring for TB on therapy—perhaps annually—is wise and the use of an IGRA rather than a TST may limit the number of patients requiring preventative treatment.

## Imaging

Although imaging patterns suggestive of TB have been discussed, there are no pathognomonic skeletal radiographic features that can establish the diagnosis. Early features on radiographs may be equivocal or nonexistent. Chest radiographs are often normal or fail to show the typical posterior upper lobe cavitary infiltrates characteristic of TB.

Conventional radiography is generally a useful approach for defining bone destruction, the extent of disease, and adjacent soft-tissue lesions.[52] MRI is more effective in identifying early disease; it may help distinguish TB from other infections and neoplasm and can aid in evaluating the extent of disease.[10,90] Scintiscans with technetium and gallium may also be helpful in localizing bone and

soft-tissue lesions, but early false-negative findings are not uncommon.[91] CT can be helpful in guiding diagnostic needle biopsy. Fine-needle biopsy is an acceptable alternative to core-needle biopsy and open biopsy for the diagnosis of osteoarticular TB in both the axial and peripheral skeleton, and it has the advantage of obviating general anesthesia.[92,93] Both CT and MRI may also be helpful in monitoring therapy.[94]

## Culture

Nearly all species of *Mycobacteria* are slow growing, with M. *tuberculosis* the slowest. Other bacteria may rapidly outgrow mycobacteria if the specimen is not inoculated on special isolation media. The small number of mycobacteria found in clinically infected areas further challenges the ability to confirm mycobacterial infection and accounts for the low yield of positive Ziehl-Neelsen staining (10% to 20%) in synovial fluid and other biologic fluids.

Synovial fluid and other body fluids are less likely than tissue to yield a positive culture. If a joint is suspected of harboring TB, a synovial biopsy should be obtained. Arthroscopically derived tissue yields higher positive cultures than needle biopsies. CT-guided needle aspiration and biopsy can provide invaluable information in the case of spinal involvement. Characteristic features on tissue pathology—caseating or noncaseating granulomas ± acid-fast bacilli on special stains—may allow an early presumptive diagnosis of TB pending culture results, which may take 4 to 6 weeks to be finalized.

### Polymerase Chain Reaction

Molecular diagnostics by using polymerase chain reaction (PCR) have proved very helpful in the rapid diagnosis of pulmonary TB, demonstrating a high yield even in patients with sputum smear-negative pulmonary TB, and are now endorsed for routine use by the WHO.[95] The role of molecular diagnostic assays in extrapulmonary TB is still being defined, but the limited preliminary experience has demonstrated promise. In a small cohort of patients with vertebral osteomyelitis, multiplex PCR testing of bone biopsy specimens demonstrated 90% sensitivity and 100% specificity for tuberculous infection, illustrating the potential for this technology to provide rapid and accurate diagnosis. Similarly, multiplex real-time PCR successfully distinguished TB from brucellosis as the cause of vertebral osteomyelitis, demonstrating a sensitivity 87% and specificity of 100% in the diagnosis of TB.[96] Additional experience is necessary before these assays are the standard for diagnosis of bone and joint TB.

# TREATMENT

Appropriate management of tuberculous infections of bones and joints is complex. Selection of appropriate antituberculous agents and ongoing disease monitoring should involve comanagement with an infectious disease consultant. Nonetheless, rheumatologists should be familiar with the basic treatment principles.

Treatment of M. *tuberculosis* infections that involves the musculoskeletal system consists of the same combination chemotherapy regimens that are effective in pulmonary TB. Treatment regimens for infections of the bone and spine are typically administered for longer durations than those recommended for lung disease and other extrapulmonary sites. These longer treatment courses for musculoskeletal disease have been recommended based on poor tissue penetration of anti-tuberculous agents into osseous tissues and the higher rates of relapse associated with these infections.

Current guidelines on the treatment of TB published jointly by the U.S. Centers for Disease Control, American Thoracic Society, and Infectious Diseases Society of America recommend a 6-month course of therapy for all sites except the bone (6 to 9 months) and the central nervous system (9 to 12 months).[97] Rifampin is the critical component that allows shorter-course therapy.

The standard approach to TB therapy (both pulmonary and extrapulmonary) in the United States currently includes four drugs to start: isoniazid, rifampin, ethambutol, and pyrazinamide—also known as *IREZ* therapy. Once the bacillus is confirmed to be sensitive to INH, the ethambutol can be discontinued. Pyrazinamide is administered for 2 months, and rifampin and INH are continued for the duration of therapy.

Longer courses of therapy are required for patients who are slow to respond. Radiographic features of mycobacterial disease may not change much after 6 months of treatment, and response to treatment is based mainly on clinical features, including reduction in pain, resolution of constitutional symptoms, and emergence of increased mobility. Longer courses are also advised for cases of relapse and resistant organisms.

Surgical intervention is seldom indicated for the initial management of osteoarticular TB. Possible exceptions at presentation include patients with advanced or progressive disease or spinal kyphosis of 40 degrees or greater. *Multidrug resistant tuberculosis* (MDR-TB), which refers to isolates that are resistant to isoniazid and rifampin, may also provide a relative indication for surgical debridement. Patients who have extensive joint destruction and immobility after an adequate course of chemotherapy may also be candidates for surgery.

Following successful antibiotic therapy, arthroplasty of the hip and knee may be undertaken and is usually successful. Recurrence of disease in the prosthetic joint is less likely if the surgery is performed years after the infection, and the tissue obtained at surgery is culture negative. This may be impractical, however, when a patient is unable to ambulate following an adequate course of therapy. In such cases, the TB therapy is continued through surgery and for at least 3 months post-operatively. If TB recurs in the prosthetic joint, it can sometimes be managed with antibiotic therapy alone. However, in many cases, removal of the prosthesis is necessary for complete resolution of the infection.

The increasing incidence of drug-resistant TB complicates the selection of appropriate drugs.[98,99] Primary monoresistance to isoniazid occurs in approximately 8% of TB isolates in the United States. When identified, this does not substantially impact the treatment outcome. The rate of MDR-TB in the United States has been relatively stable for the past decade, 1.2%. Worldwide, 5% of TB cases were MDR-TB in 2013; 3.5% of new cases and 20.5% in previously treated individuals. The treatment of MDR-TB is

complex and often requires the use of multiple (often toxic) second-line agents for 18 to 24 months or longer. XDR-TB—that is, strains resistant to all first-line TB drugs and at least three second-line agents—has been reported by 100 countries in 2013, with particularly high rates in Kazakhstan, Iran, and South Africa.[100] On average, an estimated 9% of individuals with MDR-TB have XDR-TB. Options for treatment of XDR-TB are very limited, and the risk of treatment failure and death is high.[101]

Incomplete adherence with treatment is a particularly important risk factor for secondary drug resistance, and the likelihood of drug resistance increases following relapse after treatment. Directly observed therapy is strongly advocated to reduce the spread of infection and the frequency of drug-resistant TB.[102]

## OSTEOARTICULAR INFECTIONS CAUSED BY NONTUBERCULOUS MYCOBACTERIA

Nontuberculous mycobacteria (NTM) are ubiquitous in the environment, including soil, water, and animal reservoirs. They are not typically spread from human to human, and infections with these organisms have been reported with increasing frequency.[103] Although the majority of infections caused by these organisms are pulmonary, skin and soft-tissue infections may be seen in healthy individuals; a localized lymphadenitis may develop in children.[104] Osteoarticular infections are usually caused by either direct inoculation of the organism or spread of contiguous infection.[104] Blunt trauma has been implicated as a risk factor in cases of vertebral osteomyelitis due to NTM.[105] Nontuberculous mycobacterial infections of the musculoskeletal system may develop in immunosuppressed individuals, but these infections are much less common than TB. In contrast to TB, nontuberculous infection is more likely to cause tenosynovitis, synovitis, or osteomyelitis and less likely to cause spinal infection. A review identified only 31 cases of vertebral osteomyelitis due to NTM reported between 1965 and 2003.[106] Although there are more than 120 species of nontuberculous mycobacteria, the majority of musculoskeletal infections are caused by *Mycobacterium marinum*, *Mycobacterium kansasii*, and *Mycobacterium avium-intra-cellulare* (also called *M. avium* complex, or MAC), but cases of musculoskeletal infection with *Mycobacterium haemophilum*, *Mycobacterium chelonae*, *Mycobacterium xenopi*, and *Mycobacterium conceptionense* have also been reported.[107-111]

Three distinct patterns of musculoskeletal involvement are reported: tenosynovitis, synovitis, and osteomyelitis.[112,113] Tenosynovitis typically is seen as chronic unilateral hand and wrist swelling (Figure 111-6A-C).[114] Synovitis typically is seen as chronic indolent asymmetric swelling in a knee, hand, or wrist. A number of species have been associated with these syndromes, and the number isolated from immunosuppressed patients is growing.[11] Predisposing factors, in addition to immunosuppression and direct inoculation, include environmental exposure and pre-existing joint disease.[115]

In one recent case series of 32 cases of mycobacterial arthritis and tenosynovitis, *M. tuberculosis* was isolated exclusively from 11 patients with arthritis of large joints, whereas NTM were isolated primarily from 17 patients with tenosynovitis and only 4 patients with arthritis of large joints.[116] But musculoskeletal infections with atypical mycobacteria may be indistinguishable from *M. tuberculosis* infections, so that correct diagnosis usually requires tissue biopsy and culture. Synovial fluid, when obtainable, is typically inflammatory, and a culture may be helpful only if specific mycobacterial cultures are requested. Identification of acid-fast bacilli on smear and granulomatous inflammation from a tissue biopsy specimen often provides direction for an appropriate microbiologic investigation, but histologic features do not consistently demonstrate granuloma formation. With a compatible clinical presentation and histologic findings, mycobacterial culture, including special techniques for

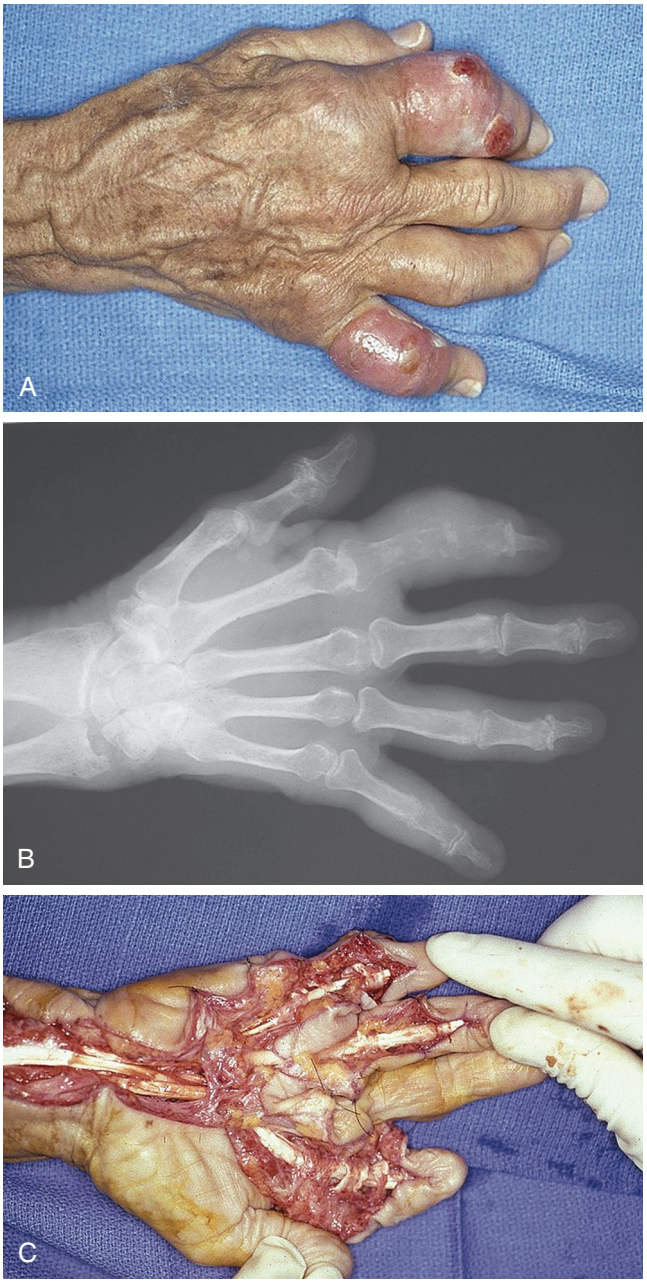

**Figure 111-6** **A,** Hand demonstrating tenosynovitis and synovitis secondary to *Mycobacterium marinum*. **B,** Radiograph of the hand in **A** demonstrates joint destruction secondary to *M. marinum*. **C,** Hand depicted in **A** and **B** shows extensive tenosynovitis at the time of synovectomy.

*M. marinum*, should be requested. Direct amplification testing may be useful for more rapid identification of mycobacterial species in tissue specimens, but data from musculoskeletal cases are limited.[117] In addition to mycobacteria, other causes of granulomatous synovitis include fungi, brucellosis, sarcoidosis, inflammatory bowel disease, and nonmetallic foreign bodies. *Mycobacteria* other than *M. tuberculosis* are responsible for a significant proportion of these cases.[118]

MAC has become the most common mycobacterial infectious agent affecting patients with HIV/AIDS, in whom it has a tendency to cause disseminated disease.[11] Fortunately, there has been a sharp decline in the incidence of MAC following the introduction of highly active antiretroviral therapy and MAC prophylaxis.

Isolation of *M. tuberculosis* is always clinically significant. In contrast, when dealing with a nontuberculous mycobacterial isolate, the clinician must judge whether it is a contaminant, represents insignificant colonization, or is the cause of disease. Certain guidelines have proven useful in this respect.[45,115,119,120]

- The illness should be consistent with one or more syndromes associated with mycobacterial infection.
- Other causes of disease, such as TB and fungi, should be excluded.
- The mycobacterial species isolated is one associated with human disease. The most significant are those that are not common environmental contaminants (*M. kansasii*, *M. marinum*, *Mycobacterium simiae*, *Mycobacterium szulgai*, *and Mycobacterium ulcerans*).
- The site of isolation of the organism should favor true infection versus contamination or colonization. (Isolation from bone biopsy, synovial tissue, or synovial fluid strongly suggests infection; isolation from the respiratory tract may represent infection or colonization.)
- Heavier growth suggests significant infection.
- Repeatedly positive cultures suggest significant infection.

Because laboratory identification of the organism and sensitivity testing may take weeks to months, initial therapy often includes multiple drugs to cover both TB and other mycobacteria. One common approach to initial empiric therapy is to link standard IREZ therapy for TB with clarithromycin until final culture results are available. The most recent American Thoracic Society guidelines for the treatment of nontuberculous mycobacteria were published in 2007.[121] Surgical debridement of infected tissue may play an important role in the treatment of selected patients, especially for resistant organisms. The most efficacious drugs remain controversial, prolonged treatment is often necessary, and relapses are not uncommon. Therapy customized to the individual patient is crucial with nontuberculous mycobacteria infection. The key to effective therapy lies in the unique characteristics of the culture and sensitivity of the particular isolate.

## EMERGENCE OF NONTUBERCULOUS MYCOBACTERIAL INFECTIONS DURING THE TREATMENT OF RHEUMATIC DISEASES

No published data exist on the risk of nontuberculous mycobacterial infections in the setting of therapy with nonbiologic disease-modifying anti-rheumatic drugs, including methotrexate. The decision to interrupt or continue therapy in such instances should be made on a case-by-case basis and should involve an infectious disease specialist, recognizing that alternative treatments, such as steroids and biologics, may carry an even greater risk.

Nontuberculous mycobacteria are increasingly recognized as important pathogens in patients receiving a TNF inhibitor. Indeed, these infections now occur twice as frequently as TB in the United States, presumably because of the use of screening tests for the latter.[122] The complexity of these infections was illustrated by a review of 239 cases of nontuberculous mycobacterial infection reported to the MedWatch database, in which only 105 were established to be probable or confirmed according to established disease criteria,[123] The most commonly reported presentation was in elderly women with RA, possibly because both nontuberculous mycobacterial infections and RA are more common in this group; most patients were also taking concomitant steroids and/or methotrexate. Infections with several different species within this group have been reported, with MAC the most common. As with TB, the risk appears to be associated with all drugs in the class, rather than a specific agent, although more infections have been reported with infliximab.[123] Extrapulmonary disease is a common finding, which is unusual for these organisms. A paradoxical response to therapy, similar to that seen with TB, has been reported with treatment of MAC following infliximab.[124] Not all patients with NTM lung disease will deteriorate on TNF inhibitor therapy, but some patients worsen despite administration of anti-NTM therapy.[125] Nevertheless, cessation of TNF inhibitor therapy should be strongly considered following the development of an atypical mycobacterial infection. Continuation or reintroduction of TNF blockers during treatment of NTM infections has been reported.[125,126]

Managing the risk of nontuberculous mycobacterial infections in the setting of TNF inhibitors treatment can be challenging. Although screening has been helpful in reducing the risk of TB infection in this setting, there is no currently available method of screening for atypical mycobacteria. Because these infections are more common in individuals with pre-existing pulmonary disease, clinicians may wish to consider more extensive evaluation of RA patients with bronchiectasis about to initiate TNF inhibitor therapy. Although MAC prophylaxis is recommended for $HIV^+$ patients with CD4 counts of 50 or less, there is no experience with, and no guidelines for, such prophylaxis with TNF inhibitor therapy. The complex nature of these infections has been further demonstrated by a case of *M. marinum* mimicking RA, with synovitis and subcutaneous nodules developing during infliximab therapy.[127]

CHAPTER 112

# Fungal Infections of Bones and Joints

Eric M. Ruderman • John P. Flaherty

**KEY POINTS**

- Fungi are an infrequent but clinically important cause of bone and joint infections.
- Fungal infections are often indolent in onset and can masquerade as other disorders.
- Travel and immigration have affected the geographic localization of several important fungal infections, which may be seen in nonendemic areas.
- Although diagnosis may be assisted by clinical presentation and serologic testing, histologic examination and culture of infected tissue are critical.
- New antifungal therapies have broadened the effective options, but choice of drugs, duration of treatment, and combined surgical débridement must be carefully considered to achieve optimal outcomes.
- Immunocompromise, including anti-rheumatic biologic therapies, may predispose to fungal infections, often resulting in more acute and widely disseminated disease.
- Screening and/or prophylactic therapy have not proven useful for patients on immunosuppressive therapy, so a high index of suspicion should be maintained when such patients are seen with an acute illness.

Fungal infection is a relatively infrequent but important cause of osteomyelitis and arthritis. Fungal diseases that commonly cause osteomyelitis include coccidioidomycosis, blastomycosis, cryptococcosis, candidiasis, and sporotrichosis (Table 112-1). Fungal arthritis is less common and is most often associated with sporotrichosis, cryptococcosis, coccidioidomycosis, blastomycosis, candidiasis, and, occasionally, other species. The epidemiology of these fungal infections, their musculoskeletal presentations, and their treatment are considered in this chapter.

The epidemiology and clinical features of individual deep mycoses may suggest the diagnosis in some cases, but their indolent presentation, which often resembles that of other noninfectious diseases, may be misleading. Travel and immigration have blurred their geographic localization. Infection may be acute and overwhelming in immunocompromised patients, for whom disseminated fungal infections are a major risk. Anti-cytokine and other immunosuppressive treatments for rheumatic diseases, particularly those targeting TNF, are associated with disseminated fungal infection,[1,2] as are HIV infection, pregnancy, and treatments for transplantation and malignancies.[3] Fungal arthritis has also been reported following intraarticular injection of contaminated preservative-free methylprednisolone.[4] For rheumatologists, disseminated fungal infections are an important diagnostic consideration in some patients and must be considered before starting biologic treatments in those at risk; they may also complicate the clinical course of other arthritides. The presentation of fungal infections as a consequence of rheumatic disease therapy will also be considered in this chapter.

Fungal infections are generally diagnosed by histologic examination or culture of involved tissues. Improved molecular diagnostic techniques may facilitate the diagnosis, provided the possibility of fungal infection is considered and proper studies are requested. Synovial fluid leukocyte counts and culture results vary among fungal infections and in individual cases and may be misleading. Serologic testing may also assist in diagnosing and staging several fungal infections. Detecting fungal antigens and DNA in blood, urine, other body fluids, and tissue may contribute to diagnosis in selected circumstances.[5]

## COCCIDIOIDOMYCOSIS

The soil fungi *Coccidioides immitis and Coccidioides posadasii* generally cause a primary respiratory illness after spores are inhaled. A self-limited acute pneumonia may result, associated with systemic manifestations such as arthralgia and erythema nodosum (valley fever), but infection is often inapparent and only infrequently becomes chronic or disseminated.[6] Coccidioidomycosis is endemic to the southwestern United States and areas of Central and South America, but cases are increasingly diagnosed in nonendemic areas because of travel and reactivation of remote infection. Cases increase when soil is disturbed and in windy conditions. Direct human-to-human transmission is rare. Extrapulmonary infection is almost always caused by hematogenous spread from an initial pulmonary focus. The bones and joints are frequent sites of dissemination, particularly in immunocompromised hosts.

Septic arthritis of the knee is common, generally arising from direct infection of the synovium. Other joint infections are caused by spread from a contiguous osteomyelitis involving the vertebrae, wrists, hands, ankles, feet, pelvis, and long bones.[7] The onset is characterized by gradually increasing pain and joint stiffness, with little swelling but early radiographic changes. In one series, arthritis was the only manifestation of disseminated coccidioidomycosis in 51 of 57 patients and was an aspect of more generalized disease in the remaining 6 patients.[8]

**TABLE 112-1** Drug Treatment of Osteoarticular Mycotic Infections

| Infection | Drug Recommended | Infection-Specific References |
|---|---|---|
| Coccidioidomycosis | Itraconazole | 3, 8, 15, 16 |
| Blastomycosis | Itraconazole | 20, 31, 133 |
| Cryptococcosis | Fluconazole | 38, 40, 133 |
| Candidiasis | Fluconazole | 50-52, 133, 134 |
| Sporotrichosis | Itraconazole | 56, 63, 64 |
| Aspergillosis | Voriconazole | 67, 72, 133 |
| Histoplasmosis | Itraconazole | 79, 86 |
| Scedosporiosis | Voriconazole | 88, 91, 92 |

Diagnostic confusion is common in osteoarticular coccidioidomycosis because of the delayed dissemination (months to years) after primary infection and because of atypical clinical presentations. The criteria for diagnosis include compatible clinical features, serologic studies, histologic examination, and culture. Enzyme-linked immunoassays for IgM and IgG are the most sensitive screening tests; immunodiffusion assays are less sensitive but more specific. Quantitative complement fixation antibody levels are useful for monitoring the effect of treatment. Serological testing for *Coccidioides* may have negative results early in the infection and in immunosuppressed patients. A specific enzyme-linked immunosorbant assay (ELISA) to *Coccidioides* galactomannan antigen in urine has shown promise in the diagnosis of severe coccidioidomycosis infection.[9,10] The definitive diagnosis is most commonly made by the demonstration of granulomatous synovitis and typical spherules in a biopsy specimen, confirmed by positive culture and direct amplification testing. Synovial fluid, when obtainable, does not necessarily demonstrate septic leukocyte counts, and may have a lymphocyte predominance. Synovial fluid is rarely culture positive; culture of synovial tissue may be more helpful. Radioisotope bone scans may be helpful to identify areas of infection.[11]

With early diagnosis of effusive synovitis, antifungal treatment alone is appropriate. Treatment is usually initiated with oral azole antifungal agents, most commonly fluconazole or itraconazole.[12] Posaconazole and voriconazole may be useful alternatives.[13,14] Amphotericin B is recommended if lesions are worsening rapidly or are in particularly critical locations, such as the vertebral osteomyelitis. Lipid formulations of amphotericin B have demonstrated less nephrotoxicity and infusion-related side effects than conventional deoxycholate amphotericin B, and they may be given at doses higher than those tolerated with conventional amphotericin, but they have never been formally studied in clinical trials. With more widely disseminated infection or involvement of critical areas such as the spine, and in high-risk hosts, the choice and duration of treatments are often complicated. Factors that favor surgical intervention are large size of abscesses, progressive enlargement of abscesses or destructive lesions, presence of bony sequestrations, instability of the spine, or impingement on critical organs or tissues (e.g., epidural abscess compressing the spinal cord).[8,15,16] Newer antifungal agents such as voriconazole and posaconazole show promise as alternative therapy.[12,14,17,18] Long-term prophylaxis with fluconazole can limit the risk for reactivation in immunosuppressed patients.

Coccidioidal synovitis can also occur as a consequence of immune complex–mediated inflammation, a presentation that may complicate either primary pulmonary or disseminated disease and is typically polyarticular. It is accompanied by fever, erythema nodosum or multiforme, eosinophilia, and hilar adenopathy. It usually abates in 2 to 4 weeks.[6,19]

## BLASTOMYCOSIS

Blastomycosis, caused by *Blastomyces dermatitidis*, is endemic in the north-central and southern United States. Infection is acquired by inhalation of conidia associated with decaying vegetation or decomposing wood and typically results in sporadic or clustered cases of acute or chronic pneumonia.[20] Affected individuals do not appear to have any distinguishing or predisposing characteristics except for exposure to the organism during work or recreation. Clinical presentation includes pulmonary, skin, and bone involvement. Approximately half of affected patients will present with fever; leukocytosis and an elevated sedimentation rate are frequently seen.[21] Bone pain, swelling, and soft-tissue abscesses are the most common manifestations of osteoarticular disease.[22] Hematogenous dissemination is common; skin disease and osteoarticular disease occur most frequently. Bone involvement occurs in 25% to 60% of disseminated cases, and arthritis is estimated to occur in 3% to 5%.[21] In a study of 45 patients with skeletal blastomycosis, 41 had osteomyelitis, whereas 12 were seen with septic arthritis.[22] In another series of 14 cases at a single institution, 12 presented as a bone mass; 3 of 4 cases of septic arthritis in this series developed because of direct extension of osteomyelitis.[23] The skeletal areas most commonly affected are the long bones, vertebrae, and ribs (Figure 112-1).[23-26] Blastomycosis often mimics malignancy with subtle constitutional symptoms, nodular lung opacities, and lytic bone lesions.

Arthritis is usually monoarticular in the knee, ankle, or elbow but may, rarely, be polyarticular.[21,27,28] Joint infection is an isolated skeletal disorder in only a few cases; joint radiographs more commonly show punched-out bone lesions (Figure 112-2A). Synovial fluid is commonly purulent, and organisms are evident on microscopic examination as well as by culture. The synovial histologic examination shows granulomas and abundant neutrophils—a so-called *pyogranulomatous tissue response*—with broad-based budding yeast forms (Figure 112-2B). The yeast can be difficult to visualize with routine hematoxylin and eosin stains, but special stains, such as the methenamine silver stain or periodic acid-Schiff (PAS) stain, can be helpful. The diagnosis is also commonly made from involved nonarticular sites. Urinary antigen testing appears to be sensitive but cross-reacts with antigens present in other endemic fungal infections.[29] For moderately severe or severe disease, treatment with amphotericin B for 1 to 2 weeks or until improvement is noted, followed by oral itraconazole for a total of at least 12 months, is recommended. For mild to moderate disease, oral itraconazole for 12 months is recommended. Serum levels of

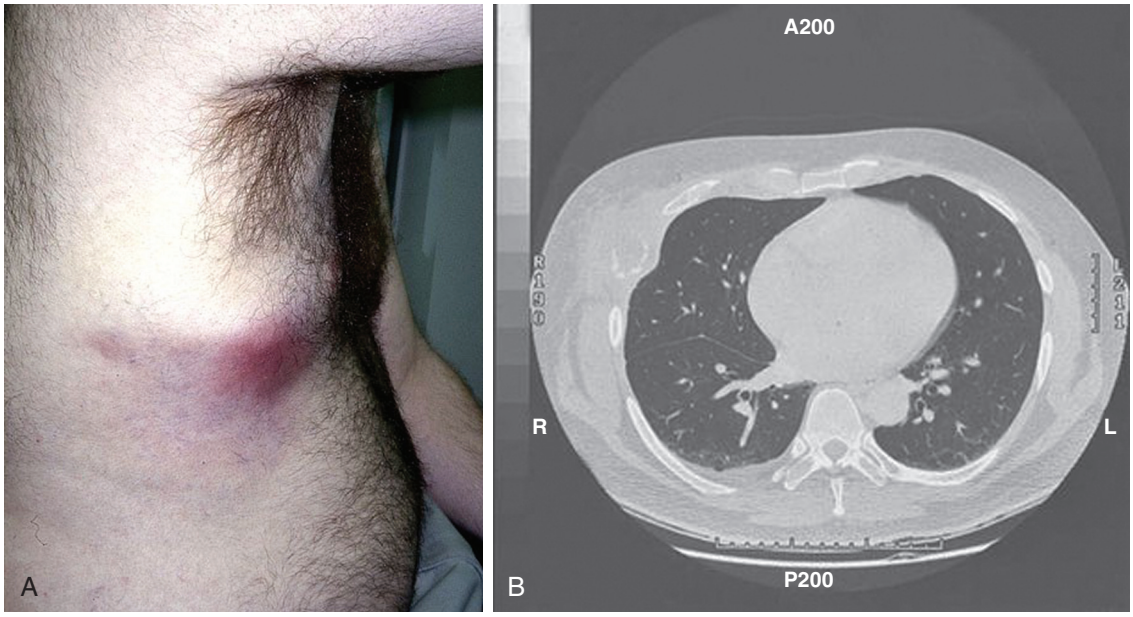

**Figure 112-1** **A,** Blastomycosis osteomyelitis of a rib and chest wall. **B,** Computed tomography scan appearance. Primary infection in the blood may spread to the skeleton.

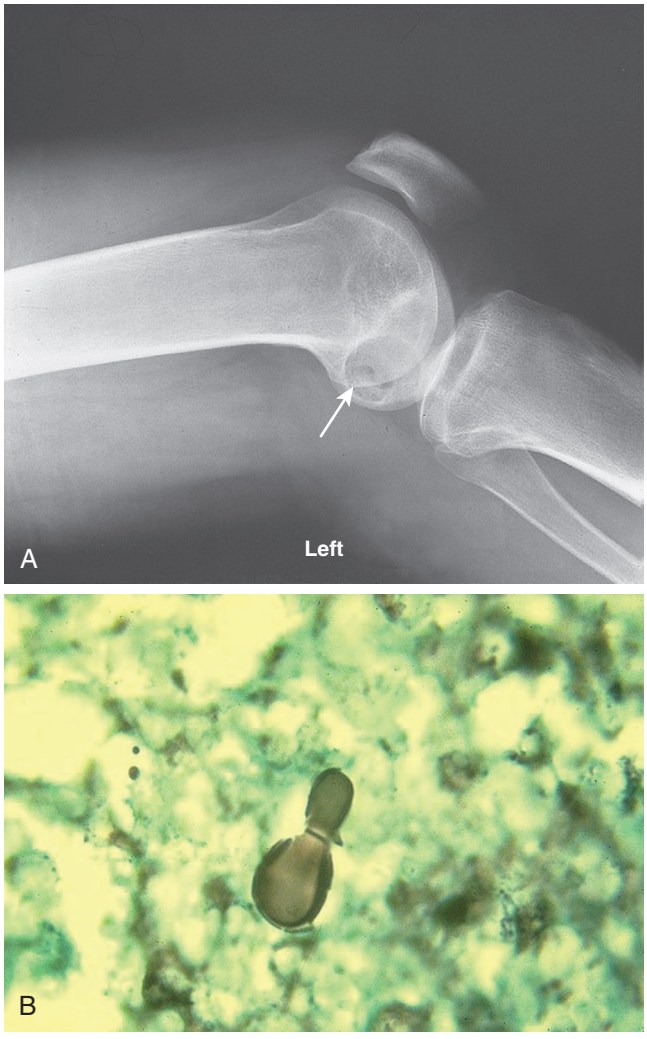

**Figure 112-2** Blastomycosis joint infection. **A,** Radiographs commonly show punched-out bone lesions. **B,** Synovial histology shows epithelioid granulomas with budding yeast forms.

itraconazole should be determined after the patient has been on treatment for at least 2 weeks to ensure adequate drug exposure.[20,30-32]

## CRYPTOCOCCOSIS

*Cryptococcus neoformans*, the fungus causing cryptococcosis, is geographically ubiquitous and is found in soil contaminated by pigeon feces; a related species, *Cryptococcus gattii*, is associated with certain types of eucalyptus trees in tropical climates and has been associated with an ongoing outbreak of disease in British Columbia, Canada, and the United States Pacific Northwest. It is a common pathogen only in association with defects in cell-mediated host defense, including HIV infection, organ and stem cell transplantation, lymphoreticular malignant neoplasms, TNF antagonist treatment,[33,34] and corticosteroid therapy.

Cryptococcosis varies in acuity, usually affecting the lungs in its primary form, but it sometimes disseminates hematogenously to a wide variety of sites, including the central nervous system and skin. Although bone infection is common, causing osteolytic lesions in 5% to 10% of cases, articular involvement is rarely reported.[35,36] As in blastomycosis, bone lesions may mimic metastatic neoplasm (Figure 112-3).

Cryptococcal arthritis is an indolent monoarticular arthritis in approximately 60% of reported cases and a polyarthritis in the remainder.[37,38] The knee is most commonly involved. A single case of tenosynovitis with carpal tunnel syndrome has been recognized. The majority of cases reported from the pre-AIDS era also demonstrated radiographic evidence of periarticular osteomyelitis. These patients were young adults, did not have debilitating disease or other evidence of dissemination, and had pulmonary involvement in only 50% of cases. Synovial tissue showed acute and chronic synovitis, multinucleate giant cells, prominent granuloma formation, and large numbers of budding yeast with special stains. Most recently reported

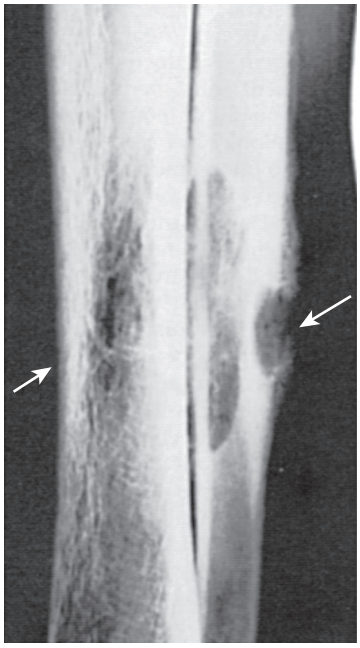

**Figure 112-3** Cryptococcosis (torulosis). Discrete osteolytic foci with surrounding sclerosis and, in some places, periosteal reaction are seen *(arrows)*. This involvement of bone protuberances such as the calcaneus is not unexpected in this disease. The resulting appearance simulates that of other fungal diseases, especially coccidioidomycosis, as well as neoplastic disorders. *(From Resnick D:* Diagnosis of bone and joint disorders*, ed 3, Philadelphia, 1995, WB Saunders, p 2507.)*

cases are associated with immunosuppression and disseminated infection. Interestingly, osteoarticular cryptococcal infections have been linked to sarcoidosis, although it is unclear whether this association relates to the immunologic impact of the sarcoidosis or to the immunosuppressive therapies used to treat it.[39] Serum cryptococcal antigen testing appears to be very sensitive, in part because osteoarticular infection results from hematogenous dissemination. The choice of treatment for cryptococcal disease depends on both the anatomic sites of involvement and the host's immune status, with amphotericin B and fluconazole considered most effective.[38,40] 5-Flucytosine is typically added to amphotericin B or fluconazole for the first 2 to 4 weeks (induction therapy) in cases of severe cryptococcal infection.[41]

## CANDIDIASIS

*Candida* species are widely distributed in nature. *Candida albicans* is a normal commensal of humans, and other species can probably live in nonanimate environments such as soil. Since the advent of antibiotic therapy in the 1940s, and related to the common use of immunosuppression and parenteral lines, candidiasis has been responsible for an increasing incidence of mucocutaneous and deep-organ infections.[42] Osteomyelitis, although uncommon, is a potentially serious complication of hematogenous dissemination in both adults and children.[43-45] A recent review identified a history of preceding candidemia in half of osteomyelitis cases, whereas it was the first proven site of infection in the other half.[46] It may also occur from direct tissue inoculation during surgery or by injection of contaminated heroin,[47] and bone infection may emerge after successful treatment of infection at other sites. Bone infection is commonly located in two adjacent vertebrae or in a single long bone. Surgical inoculation has occurred in the sternum, spine, and mandible. A few patients have had multiple sites of involvement. Candidal prosthetic joint infections may also occur as a late consequence of total joint replacement.[48]

The usual clinical presentation is localized pain. Other symptoms and laboratory abnormalities vary. It can present months after an episode of fungemia, and clinical manifestations tend to be milder than bacterial infections at the same sites. This can lead to long delays in diagnosis. Bone changes of osteomyelitis are commonly demonstrated in radiographs of the symptomatic site. The diagnosis is established when culture of involved bone obtained by either open or needle biopsy has identified a variety of *Candida* species. *Candida albicans* causes the majority of infections, but the role of nonalbicans species has been increasing in recent years.[45] Polymerase chain reaction (PCR) testing of blood may allow earlier diagnosis of disseminated Candida infection.[49] Treatment with azoles (fluconazole, itraconazole, voriconazole or posaconazole), echinocandins (caspofungin, micafungin, or anidulafungin) or amphotericin B formulations can be effective.[50,51] Species identification and susceptibility testing assist antifungal therapy selection. For example, *Candida glabrata* frequently demonstrate reduced susceptibility to azole antifungal agents and amphotericin but remain susceptible to echinocandins; *Candida krusei* are often resistant to azoles and may show reduced susceptibility to amphotericin but also remain susceptible to echinocandins; *Candida lusitaniae* are often resistant to amphotericin; and *Candida parapsilosis* may demonstrate reduced susceptibility to echinocandins.[51] The use of surgical débridement must be individualized. With vertebral involvement but no neurologic complications, medical therapy alone has been effective.

Candidiasis is an uncommon cause of monoarticular arthritis.[52] *Candida albicans* is the most common pathogen, although septic arthritis due to other candidal species has been reported.[53] Reported cases commonly involve a knee, occur in the context of multifocal extra-articular Candida infection, and are accompanied by constitutional symptoms. Both children and adults have been affected. Predisposing conditions include gastrointestinal and pulmonary disorders, narcotic addiction, intravenous catheters, leukopenia, immunosuppressive treatment (including TNF antagonists), broad-spectrum antibiotics, and corticosteroids. Some involved joints were previously affected by arthritis, and infection has followed arthrocentesis in isolated cases. In most cases, radiographs reveal coincident osteomyelitis. Synovial fluid leukocyte counts may vary; *Candida* species have been cultured from synovial fluid in all cases but are not commonly identified on smear. Histologic studies of synovium show nonspecific chronic inflammation rather than granulomas.

## SPOROTRICHOSIS

Sporotrichosis is caused by *Sporothrix schenckii*, a saprophyte found widely in soil and plants. Infection in humans occurs through inoculation of the skin or, rarely, inhalation into the respiratory tract; it is a source of infection among

agricultural workers in tropical and subtropical areas. It most commonly involves the skin and lymphatics but may disseminate from the lungs to the central nervous system, eyes, bones, and joints.[54] In immunocompetent hosts, a single site is typically involved; in immunocompromised hosts, including patients on anti-cytokine therapy, multifocal disease may occur.[55]

In contrast to the relatively common occurrence of skin infection, articular sporotrichosis is a rare disorder.[56,57] In 84% of patients in one series, there was no accompanying skin involvement, suggesting entry through the lungs. Sporotrichosis most often occurs in individuals with a chronic illness that alters host defense, such as alcoholism or a myeloproliferative disorder. *Sporothrix* arthritis is most often indolent and infects a single joint or multiple joints in equal proportions. The knee, hand, wrist, elbow, and shoulder are most frequently involved; hand and wrist involvement distinguishes this from other fungal arthritides. Articular infection shows a propensity to spread to adjacent soft tissues, forming draining sinuses. Constitutional symptoms are unusual.

Radiographic changes vary from juxta-articular osteopenia to the commonly observed punched-out bone lesions. When it can be obtained, synovial fluid is inflammatory. Synovitis is characterized on gross evaluation by destructive pannus and on microscopic examination by granulomatous histologic features or, less frequently, by nonspecific inflammation. Organisms are difficult to identify in tissue, and the diagnosis is often made by positive culture of joint fluid or involved tissue. Incubation at room temperature facilitates growth of the mycelial phase of *S. schenckii*. Serologic testing is not useful in the diagnosis of sporotrichosis. In a small number of cases, sporotrichosis may disseminate to cause a potentially fatal infection characterized by low-grade fever, weight loss, anemia, osteolytic bone lesions, arthritis, skin lesions, and involvement of the eyes and central nervous system.[58-61] These infections occur in immunosuppressed patients with either hematologic malignancies or HIV infection.

In 44 cases reported in 1979, treatment was optimal with combined joint débridement and high-dose intravenous amphotericin B (11 of 11 cured) and slightly less effective with amphotericin alone (14 of 19 cured).[56] More recently, itraconazole has proven effective for initial therapy of most patients,[62] with amphotericin B reserved for those with extensive involvement and for itraconazole failures. In contrast, fluconazole has demonstrated only modest success in osteoarticular sporotrichosis.[63,64]

## ASPERGILLOSIS

*Aspergillus* species are ubiquitous, but infection occurs only rarely in immunocompetent individuals. In contrast, invasive infection is an important life-threatening complication in immunocompromised adults and children.[65-69] It may spread directly from the lung to adjacent vertebrae, disk spaces, and ribs (more often in children) or through the bloodstream (Figure 112-4).[70-72] Rare cases of monoarthritis with adjacent osteomyelitis are also reported. The knee is the most commonly involved joint. The organism may be observed in infected tissue (see Figure 112-4B). The galactomannan ELISA has been validated as a surrogate marker

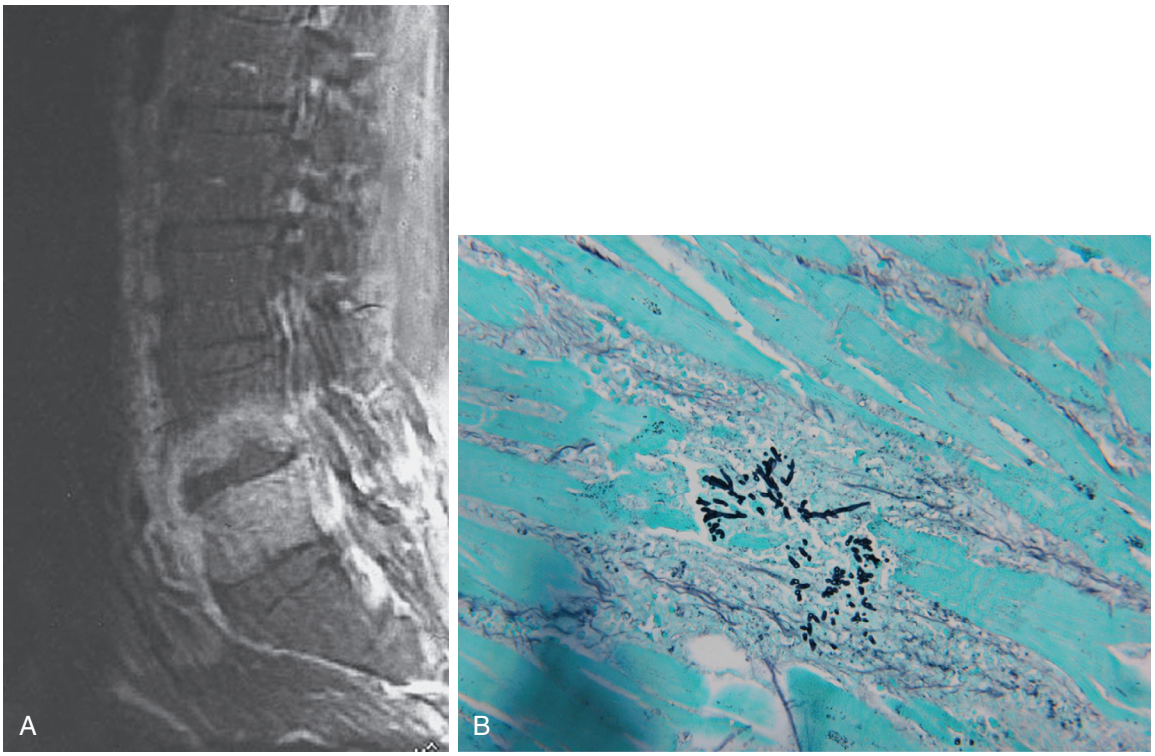

**Figure 112-4** Aspergillosis vertebral osteomyelitis and diskitis. **A,** *Aspergillus* may spread directly from the lung to adjacent vertebrae, disk spaces, and ribs (more often in children) or through the bloodstream. **B,** Infected tissue may show characteristic organisms.

for invasive aspergillosis, and the (1→3)-β-D-glucan assay similarly may provide support for the diagnosis of invasive fungal infection. Treatment with combined surgical débridement and antifungal therapy is an ongoing challenge.[66,71,73] Voriconazole has proven superior to amphotericin for the treatment of invasive aspergillosis and is now recommended for initial therapy.[74,69,73] Liposomal amphotericin B, posaconazole, caspofungin, and micafungin have demonstrated efficacy in salvage situations.[75] Combination therapy has not demonstrated clear improvement in outcomes versus monotherapy. In 2012, an outbreak of fungal infections, initially believed to be due to *Aspergillus fumigatus* but later attributed to the rarely pathogenic fungus *Exserohilum rostratum*, was traced to contaminated injectable methylprednisolone produced by a single compounding pharmacy in Massachusetts.[4,76] The index case involved *A. fumigatus* meningitis following an epidural injection; subsequent cases included meningitis, stroke, and musculoskeletal infections, including vertebral osteomyelitis, diskitis, and facet joint infections.[77,78]

## HISTOPLASMOSIS

*Histoplasma capsulatum* is a soil fungus that causes endemic disease in the Midwest and Southeast United States.[37,79] Bone and joint involvement is rare but has been reported in the knee, wrist, and ankle. Immunosuppression, including the use of TNF inhibitors predisposes to disseminated histoplasmosis in adults and children, which may be confused clinically with sarcoidosis, tuberculosis, and reactive inflammatory conditions.[80-83] Diagnosis depends on appropriate use of fungal staining and culture methods and antigen detection.[84] A case report emphasizes the rare occurrence of fungal prosthetic joint arthritis.[85] The more common osteoarticular involvement with histoplasmosis is a hypersensitivity syndrome accompanying acute pulmonary infection; it is characterized by self-limited polyarthritis, erythema nodosum, and erythema multiforme. Liposomal amphotericin B followed by itraconazole is the preferred treatment for severe infection and itraconazole for less severe cases.[79,86,87]

## SCEDOSPORIOSIS

*Scedosporium* species are environmental molds that have been identified as fungal pathogens in both immunocompetent and immunocompromised hosts. They may cause focally invasive and disseminated infection after cutaneous inoculation. *Scedosporium prolificans* has a predilection for bone and cartilage, leading to both septic arthritis and osteomyelitis. Infections are difficult to eradicate with surgery and antifungal agents, and the organism is resistant to amphotericin.[88,89] Case reports suggest improved infection control with voriconazole or voriconazole combined with terbinafine.[90-92]

## TREATMENT OF FUNGAL INFECTION

Antifungal chemotherapy has improved over the past several decades, first with the introduction of amphotericin B and then with the oral antifungal agents flucytosine, ketoconazole, fluconazole, and itraconazole. More recent advances include the development of less toxic formulations of amphotericin B, liposomal amphotericin B, and amphotericin B lipid complex. Voriconazole and posaconazole, which are broad-spectrum azole antifungals, have demonstrated improved activity against aspergillosis and mucormycosis, respectively. The echinocandin antifungal agents caspofungin, micafungin, and anidulafungin have emerged as alternative therapies for aspergillosis and as the treatments of choice for some *Candida* infections. For detailed treatment guidelines, several excellent reviews are available.[93-103] In choosing an appropriate drug (Table 112-2) and course of treatment, the clinician must consider the infecting agent, clinical manifestations of the disease, immune status of the host, anti-microbial resistance, drug side-effect profile, and direct and indirect costs of treatment. Treatment has become more complex because of immune system compromise in infected patients treated for transplant rejection, autoimmune disorders, malignant disease, and AIDS.[104]

Itraconazole has become the first choice for treatment of the endemic mycoses—blastomycosis, histoplasmosis, and sporotrichosis. A loading dose of itraconazole of 200 mg three times a day for 2 days is recommended, followed by 200 mg to 400 mg daily. Absorption of itraconazole is unpredictable and blood levels of itraconazole should be measured to ensure adequate drug exposure. Absorption of itraconazole requires stomach acid, so concurrent administration of drugs that reduce the acidity of the stomach such as proton pump inhibitors and $H_2$ blockers should be avoided. At least 6 months of treatment is required, and some patients may need as long as a year of therapy. For cryptococcosis, fluconazole is the recommended azole.[38,40] Amphotericin B is the preferred drug for meningeal and life-threatening infections. Specific treatment protocols and detailed side effect profiles are presented in reviews,[93-102] Infectious Diseases Society of America guidelines,[12,32,41,51,75,87] and infection-specific references (see Table 112-2). Surgical débridement is critically important in the treatment of mucormycosis and may be of value as adjunctive treatment for certain fungal infections, including selected patients with invasive aspergillosis and vertebral osteomyelitis caused by coccidioidomycosis, especially when there is evidence of spinal cord impingement or progression on repeat imaging on antifungal therapy. Surgery does not play a major role in the treatment of blastomycosis, histoplasmosis, or *Pneumocystis jiroveci* infection.

**TABLE 112-2** Disseminated Fungal Infections Reported with TNF Inhibitor Therapy

| Organism | References |
|---|---|
| Aspergillosis | 1, 55, 115 |

| Sporotrichosis | 55 |

## FUNGAL INFECTION AS A CONSEQUENCE OF ANTI-RHEUMATIC THERAPY

Many of the same fungal infections associated with osteoarticular disease may cause infection in patients treated with anti-rheumatic therapy, particularly biologic therapy. Animal models of infection point to an important role for TNF in host defense against many of these organisms, including *Aspergillus*,[105] *Candida*,[106] *Cryptococcus*,[107,108] *Coccidioides*,[109] and *Sporothrix*.[110]

Coccidioidomycosis infection following TNF inhibitor therapy has been reported in endemic areas in the Southwest United States. In the largest published series, 12 of 13 cases followed therapy with infliximab, and 1 was associated with etanercept.[111] All but 2 of these cases were believed to represent new infection rather than reactivation. In one medical center included in this series, the relative risk of coccidioidomycosis infection was 5.23 with infliximab therapy compared with other anti-rheumatic therapy. In all cases, coccidioidomycosis infection developed in the absence of other known risk factors, including diabetes, pregnancy, and HIV infection. Updated data from the same institutions, however, has suggested that biologic or nonbiologic disease-modifying anti-rheumatic drug (DMARD) treatment can potentially be reinstituted during or after antifungal therapy.[112] Coccidioidomycosis infection has also been reported in nonendemic areas, presumably as a consequence of fomite exposure.[113]

Disseminated histoplasmosis infections have been reported following TNF inhibitor therapy in endemic areas in the Ohio-Mississippi River valley regions of the central United States; as with coccidioidomycosis infections, these have been reported more frequently following infliximab therapy than with the other agents.[80] The reason for the larger number of cases with infliximab is unclear; possibilities include a unique mechanism of action for infliximab, larger numbers of patients treated, patient selection, concomitant immunosuppressive therapy, or some combination of all of these. In most cases, patients in whom disseminated histoplasmosis with TNF antagonist therapy develops have been taking additional immunosuppressive therapy. In a series of 26 patients with histoplasmosis and rheumatoid arthritis (RA), TNF inhibitors (including adalimumab, etanercept, and infliximab), methotrexate, and corticosteroids were all implicated as potential contributing factors.[114] Patients typically are seen with cough, dyspnea, fever, and malaise, and can rapidly become quite ill. Histoplasma antigen may be identified in the urine in 92% of patients with disseminated histoplasmosis, and this test may facilitate rapid diagnosis.[82] Exposure to *Histoplasma* may result in asymptomatic latent infection; it has been difficult, however, to determine whether symptomatic infections following TNF inhibitor therapy represent reactivation or new infection. Both pulmonary and disseminated infections with cryptococcal infections have been reported with TNF antagonist therapy, as have infections with *Aspergillus, Candida, Scedosporium, and Sporothrix*.[1,33,55,115-118] Fungal infections have not been reported as a consequence of abatacept or rituximab therapy in rheumatic diseases. Whether this relates to decreased risk with these agents or smaller numbers of patients treated remains to be seen.

*Pneumocystis jiroveci* pneumonia (PCP) is caused by a fungus originally classified as a protozoan (*Pneumocystis carinii*). PCP, an opportunistic infection seen in association with HIV infection, has been reported with a number of anti-rheumatic therapies, including cyclophosphamide and low-dose methotrexate, often in combination with corticosteroid therapy.[119,120] Interestingly, PCP as a consequence of low-dose methotrexate therapy has been reported as a particular concern in Japan, where the prevalence of asymptomatic carriage of pneumocystis has been reported to be as high as 18.8% in the elderly.[121] These same authors have suggested that PCR testing may identify carriers at increased risk for PCP during therapy.[122] The use of biologic therapy, including rituximab[123] and TNF inhibitors,[124] has been associated with the development of PCP. Patients with PCP are seen with fever, dry cough, and dyspnea. The clinical presentation in patients receiving immunosuppressive therapy is typically more acute than in HIV-associated cases. Organisms may be identified in sputum from patients with HIV but are seen less commonly in rheumatologic patients. A presumptive diagnosis may be made on the basis of PCR testing for *P. jiroveci* DNA. Elevated serum levels of β-D-glucan, a common component of fungal cell walls, may aid in the diagnosis. One series of 21 patients identified older age, pre-existing pulmonary disease, higher corticosteroid doses, and low serum albumin and IgG levels as potential risk factors for PCP in patients treated with infliximab.[124] Chest radiographs may show diffuse infiltrates, whereas CT scans demonstrate ground-glass opacities (Figure 112-5 and Figure 112-6). Radiographic findings may be difficult to distinguish from methotrexate pneumonitis. Treatment includes supplemental oxygen and trimethoprim/sulfamethoxazole (TMP/SMX) or pentamidine isethionate. High-dose corticosteroids are commonly used as adjunctive therapy in the treatment of HIV$^+$ patients with PCP but are less well studied in patients taking immunosuppressives.

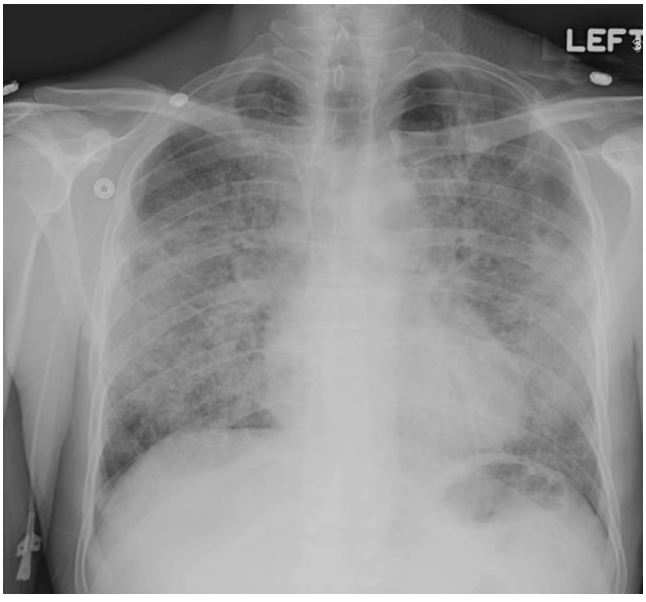

**Figure 112-5** Chest radiograph showing diffuse interstitial infiltrate in a patient with *Pneumocystis jiroveci* pneumonia.

**Figure 112-6** Computed tomography scan of the chest demonstrating ground-glass opacity in a patient with *Pneumocystis jiroveci* pneumonia.

PCP infection is also of concern with nonbiologic immunosuppressive therapy. In particular, the use of cyclophosphamide to treat systemic lupus, vasculitis, and other autoimmune diseases has been associated with a risk for PCP, although the overall risk appears to be low. In a recent review of published data on 76,156 patients with SLE, the risk of PCP was 15.88 per 10,000 patients, or 0.158%.[119] Potential risk factors include high-dose corticosteroid use, lymphopenia (especially low CD4 counts), renal disease, and overall high disease activity.[119,125] Patients with vasculitis with pulmonary involvement may be at increased risk, and diagnosis may be difficult in both these patients and patients with lupus with pulmonary disease. Unfortunately, there are no published guidelines to address the use of PCP prophylaxis in autoimmune diseases, nor a clear consensus regarding the standard of care in this situation. Recent clinical trials in vasculitis have routinely used PCP prophylaxis as part of the protocol, suggesting it is becoming standard of care.[126] Two recent surveys of U.S. rheumatologists, however, found that just 50.4% and 69.5%, respectively, routinely prescribed prophylactic antibiotics.[119,127] Academic rheumatologists and more recent graduates are more likely to prescribe prophylactic therapy. TMP/SMZ appears to be more effective than dapsone or aerosolized pentamidine, despite an apparent increased risk of sulfonamide allergy in the lupus population.[128,129] There are no consistent standards, or recommendations, for the use of prophylaxis for fungal infection other than *Pneumocystis*.

Unlike mycobacterial infection, biologic therapy of rheumatic disease has not been definitively associated with an increased overall risk of fungal infection, although the lack of a statistically significant association with these rare infections cannot disprove a possible connection.[130] Indeed, fungal infections have been reported in a post-marketing biologic registry in France.[131] In general, patients with a history of fungal infection, or those with significant exposure to these organisms, should receive biologic therapy only when alternatives are not available or appropriate. Patients should be cautioned to minimize exposure to sources of infection during therapy (e.g., avoid exposure to histoplasmosis in old buildings [demolition, remodeling, cleaning], chicken coops, bird roosts, wood piles, or caves [spelunking] and avoid exposure to outdoor dust in regions endemic for coccidioidomycosis). There is, as yet, no practical role for screening for latent infection or for prophylactic therapy.[132] Serologic tests and delayed-type hypersensitivity testing do not distinguish past, resolved infection from latent infection, although repeat coccidiomycosis serologies has been proposed as part of an algorithm for determining the potential safety of reinstituting biologic therapy after treatment of an acute, nondisseminated infection.[112] Chest radiographs may identify calcified granulomas consistent with prior histoplasmosis infection, but this is a nonspecific finding. In Japan, it has been suggested that TMP/SMX therapy might normalize PCR testing in asymptomatic *P. jiroveci* carriers treated with methotrexate, and that this might reduce the risk of developing pneumonia, but this has not been studied in a U.S. population.[122] The lack of useful screening tests makes early recognition of infection and institution of therapy critical. Indeed, the FDA has mandated a "black box" warning regarding the risk of fungal infections on the product labels of TNF inhibitors, reflecting the potentially fatal consequences of delayed recognition of such infections.

CHAPTER 113

# Rheumatic Manifestations of Human Immunodeficiency Virus Infection

John D. Reveille

**KEY POINTS**

- Because patients with HIV living longer as a result of more effective treatments, the challenges of HIV-associated rheumatic manifestations are growing.
- Certain diseases are specific to HIV infection (i.e., HIV-associated arthritis, diffuse infiltrative lymphocytosis syndrome [DILS], HIV-associated polymyositis).
- Other diseases, such as diseases that involve $CD4^+$ T cells including rheumatoid arthritis and systemic lupus erythematosus, tend to go into remission with HIV activity and to flare with anti-retroviral treatment.
- Effective anti-retroviral therapy decreases the prevelance of certain diseases (i.e., DILS, late opportunistic infections) but also is associated with side effects (e.g., osteonecrosis, myopathy, rhabdomyolysis).
- With immune reconstitution after anti-retroviral therapy, a new spectrum of autoimmune and autoinflammatory diseases has emerged that requires careful attention.

In the years since AIDS was initially described in 1981, the HIV pandemic has become one of the leading global health crises. According to new data in the Joint United Programme on HIV/AIDS (UNAIDS) 2013 report[1] the AIDS epidemic seems to be slowing down globally, with people living longer and new infections decreasing, although still occurring at alarming rates in certain regions such as southern Africa, eastern Europe, and central and eastern Asia. An estimated 35.3 million people worldwide are living with HIV (Figure 113-1). Approximately 2.3 million people became newly infected with HIV in 2012, and 1.6 million people died.

Progress in dealing with the HIV epidemic, including progress in education and in public health awareness, has undoubtedly influenced the decrease in new infections seen among young people in some countries in recent years. While availability of newer treatment strategies and better access to health care resulting in increased life expectancy has ensued, infection will be managed increasingly as a chronic illness, and complications such as musculoskeletal and rheumatic conditions associated with HIV infection and its treatment are expected to increase (Table 113-1 and Table 113-2).

Among the rheumatologic disorders, clinicians face the challenge of treating potentially disabling inflammatory disorders with immunosuppressive therapy in the face of ongoing viral-induced immunocompromise. Diagnosing infection is especially important in an immunocompromised patient because the probability of an opportunistic infection as a cause for a musculoskeletal complaint increases with advancing stages of the patient's HIV disease. At early stages ($CD4^+$ count >300/μL), opportunistic infections are unlikely, although bacterial infections (especially tuberculosis) still can occur. There should be a very high threshold for using immunosuppressive drugs in this population.

## HIV-ASSOCIATED BONE AND JOINT DISEASE

### HIV-Associated Arthralgia

As many as 25% of $HIV^+$ patients in recent series may have otherwise unexplained arthralgia.[2,3] Arthralgias and myalgias also form a part of the constitutional symptoms of HIV seroconversion. Whether arthralgia can be attributed to circulating viral and host immune complexes caused by HIV infection per se or to other infections (e.g., hepatitis C) has not been determined. The pathogenesis is unclear but may involve cytokines or transient bone ischemia.[4] However, patients presenting with arthralgia alone rarely progress to inflammatory joint disease. The most appropriate treatment consists of non-narcotic analgesics and reassurance.

### Painful Articular Syndrome

Painful articular syndrome is a self-limited syndrome lasting less than 24 hours, associated with few objective clinical findings, and characterized by severe bone and joint pain.[2-4] It occurs predominantly in the late stages of HIV infection. Its cause is unknown, and no evidence of synovitis has been found in these patients. The knee is most commonly affected, but the elbow and shoulders also can be involved. Radiographic features are nonspecific; occasionally, periarticular osteopenia is seen. Treatment is symptomatic. Given the abrupt nature of this disorder's onset, these patients are more likely to be encountered in emergency rooms and not in HIV clinics.

### HIV-Associated Arthritis

The first reports of a seronegative arthritis associated with HIV infection appeared in 1988,[4] with frequencies of 12%. HIV-associated arthritis is most common in sub-Saharan Africa, where HIV infection is pandemic. In the Congo, where the seroprevalence of HIV infection is 7% to 8%, AIDS is the leading cause of aseptic arthritis (60% of

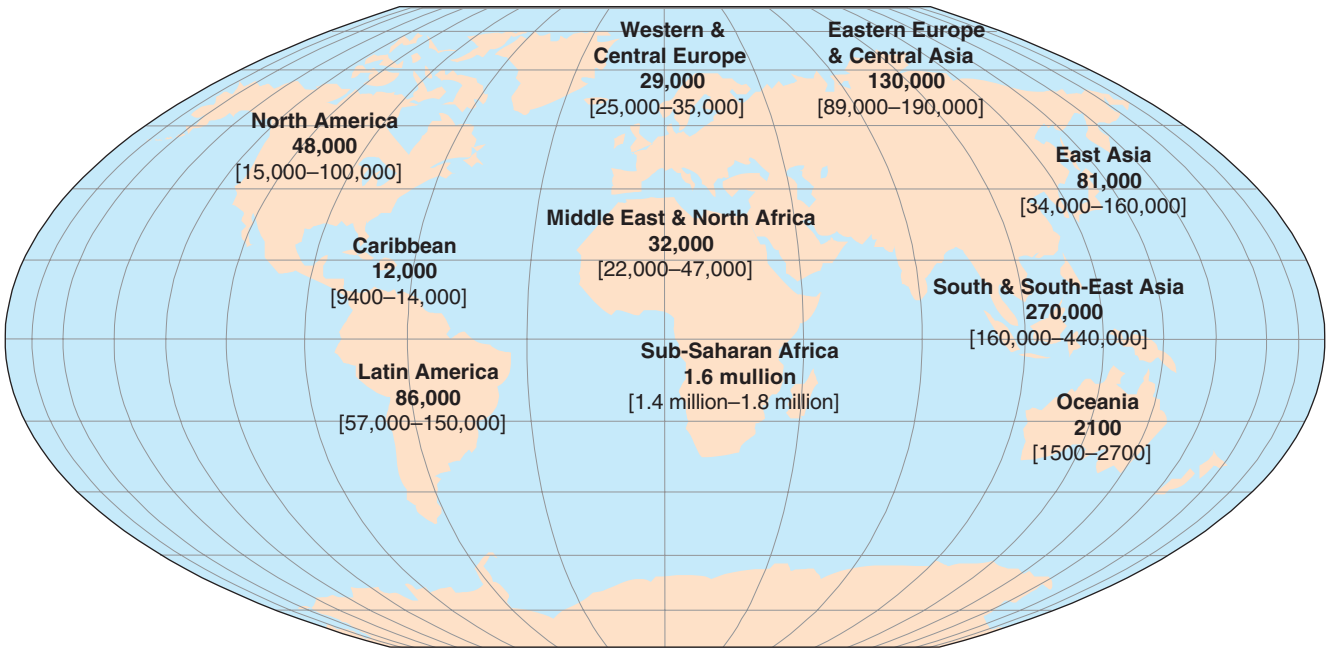

**Figure 113-1** A global view of human immunodeficiency virus (HIV) infection—33 million living with HIV in 2012. *(From UNAIDS: 2013 Report on the Global AIDS Epidemic [website]:* http://www.unaids.org/en/resources/campaigns/globalreport2013/globalreport/*.)*

| Systemic lupus erythematosus |
| Sarcoidosis |

IRIS, Immune reconstitution inflammatory syndrome.

cases).[5] This is usually an oligoarthritis (Table 113-3), predominantly involving the lower extremities, and tends to be self-limited, lasting less than 6 weeks.[4,6] Most commonly involved are the knees (84%), ankles (59%), and metatarsophalangeal joints (23%) in the lower limbs, and the wrists (41%), elbows (29%), and metacarpophalangeal and interphalangeal joints (25%) in the upper limbs, similar to other viral arthritides. Some patients have been reported as having a longer course, with joint destruction.[7,8]

The origin is unclear; no association has been noted with human leukocyte antigen (HLA)-B27 or any other known genetic factor. Synovial fluid cultures are typically sterile, although one report described the presence of tubuloreticular inclusions, suggesting a viral origin, possibly HIV itself.[4] Radiographs of affected joints are usually normal, except in uncommon cases with prolonged symptoms, in which joint space narrowing and destruction can occur. Treatment includes NSAIDs and, in more severe cases, low-dose glucocorticoids. Hydroxychloroquine and sulfasalazine also have been used.[9]

## Reactive Arthritis Occurring in HIV Infection

Early reports in the United States suggested that reactive arthritis occurred more commonly in the setting of HIV infection; however, later studies showed that this may be reflective of the sexually active nature of the population at highest risk for HIV infection.[10] This contention is not borne out in studies from sub-Saharan Africa, where HLA-B27 is rare, as were reports of spondyloarthritis before the HIV epidemic. With the arrival of AIDS, a dramatic upsurge in the prevalence of reactive arthritis and undifferentiated spondyloarthritis and, less often, psoriatic arthritis,[8,11] was seen, suggesting a pathogenic role of HIV infection.

The typical presentation is a seronegative lower-extremity peripheral arthritis, usually accompanied by enthesitis (dactylitis, Achilles tendinitis, and plantar fasciitis). Mucocutaneous features are common, especially keratoderma blennorrhagicum (Figure 113-2) and circinate balanitis. Extensive psoriasiform skin rashes can occur. The clinical overlap makes it difficult sometimes to distinguish HIV-associated reactive arthritis from psoriatic arthritis.[12] Urethritis occurs in similar frequency as in HIV$^-$ reactive arthritis. Axial involvement and uveitis seem to be less common but do occur. Longitudinal studies from Africa have described an aggressive course with a poor prognosis.[13,14]

**TABLE 113-2** Distribution of Various Rheumatic Diseases in HIV$^+$ Patients from Various Sites

| Feature | Cincinnati, Ohio (until 1993) | Houston, Texas (1994-2002) | Bangkok, Thailand (2005) | Taiwan (1993-2013) | Darjeeling, India (2010-2011) |

| Human leukocyte antigen-B27 association | Absent | 70%-90%† |

*Shown in non–HIV-associated reactive arthritis. Reports of such infections in patients with HIV-associated reactive arthritis are lacking.
†In whites.

**Figure 113-2** Keratoderma blennorrhagicum in a patient with reactive arthritis and HIV infection.

HLA-B27 is found in 80% to 90% of patients with HIV-associated reactive arthritis, at least among whites.[12] Studies from Africa have found most patients to be HLA-B27$^-$, however.[8,11] It has been known for more than 20 years that the presence of HLA-B27 antigen is associated with slower progression to AIDS.[13] In asymptomatic HIV-infected, HLA-B27$^+$ individuals, cytotoxic T lymphocyte responses are dominated by recognition of a gag-encoded p24 protein epitope that is not seen in HIV$^+$, HLA-B27$^-$ individuals.[14,15] Other class I HLA antigens that have been associated with a better outcome in HIV infection have been implicated in psoriasis and psoriatic arthritis and include HLA-B13 and HLA-B57.[13,14] Approximately half of Caucasian long-term nonprogressors have either HLA-B57 or HLA-B27.[15] Other genetic and innate immune factors associated with nonprogression include delta32 CCR5 allelic associations HLA-C/KIR interactions.[15] HLA-B*5703 was protective against HIV progression in a Zambian population but conferred susceptibility to spondyloarthritis.[16]

## Treatment

Treatment is similar to that for HIV$^-$ patients with reactive arthritis. NSAIDs are the mainstay; in particular, indomethacin is recommended, not only for its efficacy, but also for its inhibition of HIV replication that has been observed in vitro, which seems to be unique to this NSAID.[17] Patients frequently have an inadequate response to NSAIDs alone. Sulfasalazine was effective in some studies at doses of 2 g/day, and one study suggested that it ameliorated HIV infection.[18] Methotrexate was initially believed to be contraindicated because of its immunosuppressive effect, but with careful monitoring of HIV viral loads, CD4$^+$ counts, and the patient's clinical status, more recent studies have suggested a place for methotrexate in the treatment of reactive arthritis and psoriatic arthritis occurring in HIV infection.[19]

Hydroxychloroquine has been reported to be efficacious not only in treating HIV-associated reactive arthritis, but also in reducing HIV replication in vitro and in reducing HIV viral loads in vivo.[20] Arthritis and the cutaneous

lesions of HIV-associated reactive arthritis and psoriatic arthritis have been found to respond to etretinate (0.5 to 1 mg/kg/day),[21] although because of the side effects of this drug, its use should be reserved for patients unresponsive to other treatments. TNF blockers have been used,[22,23] although these agents should be used with extreme caution and only in patients with $CD4^+$ counts greater than 200/μL and HIV viral load less than 60,000 copies/$mm^3$.[24,25] One prospective study of eight HIV patients with spondyloarthritis or rheumatoid arthritis found TNF blockers effective and safe for as long as 5 years when these precautions were followed at initiation of therapy.[25]

## Psoriasis and Psoriatic Arthritis

The extent of skin involvement with psoriasis can be extensive (Figure 113-3) in $HIV^+$ patients, especially in patients not on anti-retroviral treatment. Of note, cutaneous T cell lymphoma can resemble psoriasis and should be considered in the differential diagnosis of psoriasis in $HIV^+$ individuals.[25] Psoriasis and psoriatic arthritis were infrequently reported in sub-Saharan Africa before the HIV pandemic, with prevalences of psoriasis (in hospital-based dermatology departments) ranging from 0.05% to 0.9% in West Africa and 2.8% to 3.5% in South Africa.[27] However, this has increased significantly in the HIV era, with more than 5% of $HIV^+$ individuals reported with psoriasis. Similarly, there were few data on psoriatic arthritis prevalence in sub-Saharan Africa. Psoriatic arthritis was reported before the beginning of the HIV pandemic (41.6% among 61 patients with psoriasis) and many feel this too has increased with the growing HIV prevalence.[26,27]

In general, the arthritis in HIV-associated psoriatic arthritis is predominantly polyarticular, lower limb, and progressive. Psoriasis is commonly an extensive guttate-plaque admixture and, in contrast to the articular disease, was nonremittive with the onset of AIDS.[27,28] Anti-retroviral treatment is effective in treating HIV-associated psoriasis and its associated arthritis.[29,30] Phototherapy may improve the skin rash but also may enhance viral replication, worsen HIV disease, and increase the risk of skin cancer. Other agents reported to be efficacious include cyclosporine (although renal function must be monitored carefully) and etretinate. Methotrexate also can be used, albeit with caution.[19] TNF blockers can be used in patients with refractory disease, and a number of patients have had dramatic improvements in skin lesions and in arthritis,[25,31] although with the usual precautions (see preceding text) because frequent polymicrobial infections while on the drug resulted in its discontinuation in some patients.[31]

**Figure 113-3** Disseminated psoriasis vulgaris in a patient with HIV–associated psoriasis.

## Undifferentiated Spondyloarthritis

Symptoms of reactive arthritis or psoriatic arthritis such as enthesopathy (plantar fasciitis, Achilles tendinitis) are observed in patients in whom full-blown disease does not otherwise develop. Treatment is symptomatic (e.g., NSAIDs, intralesional corticosteroid injections), although sulfasalazine should be considered in patients with more extensive disease.

## Avascular Necrosis of Bone

Case control studies have shown an association of osteonecrosis after the introduction of highly active anti-retroviral therapy (HAART), especially in those who have received corticosteroids.[32,33] A recent meta-analysis revealed a more than twofold increased odds of avascular necrosis (AVN) among HIV-infected patients exposed to protease inhibitors.[33] Other contributing factors, include dyslipidemia (associated with protease inhibitor usage), as well as alcohol abuse, use of megestrol acetate, the presence of antiphospholipid antibodies,[34] and intravenous drug abuse,[35] as well as HIV itself.[36] The most common presenting symptom of osteonecrosis is pain on weight bearing and activity. Some patients may be asymptomatic, and the diagnosis is made based on incidental findings in radiologic studies. Most patients tend to present when subchondral collapse already has occurred. Radiographs, computed tomography (CT), MRI, and nuclear medicine studies have been used successfully to diagnose osteonecrosis, as in $HIV^-$ patients.

## Hypertrophic Pulmonary Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy affects bones, joints, and soft tissues and can develop in HIV-infected patients with *Pneumocystis jiroveci* pneumonia. It is characterized by severe pain in the lower extremity; digital clubbing; arthralgia; nonpitting edema; and periarticular soft tissue involvement of the ankles, knees, and elbows. The skin over the affected areas is glistening, edematous, and warm. Radiography reveals extensive periosteal reaction and subperiosteal proliferative changes in the long bones of the lower extremity. A bone scan shows increased uptake along the cortical surfaces. Treatment of *P. jiroveci* pneumonia usually alleviates this condition.[37]

### Osteopenia and Osteoporosis

Osteopenia and osteoporosis occur more than three times as commonly in HIV-infected patients regardless of antiretroviral treatment[38] and can result in pathologic fractures.[39] One meta-analysis found 15% of HIV$^+$ patients to have osteoporosis and 52% to have osteopenia.[40] Risk factors for osteopenia include use of protease inhibitors, advanced stage of HIV infection, high viral load, low body mass, low bicarbonate levels, increased alkaline phosphatase levels, and especially, smoking and Vitamin D deficiency.[41,42] Clinicians should have a low threshold to screen for vitamin D deficiency, should provide adequate repletion as necessary, and (if not done already for many other reasons) counsel against smoking. Bisphosphonates and, in patients with HIV wasting syndrome, testosterone, have been used to preserve bone density.[43]

## HIV-ASSOCIATED MUSCLE DISEASE

Muscle involvement in HIV infection varies from uncomplicated myalgias or asymptomatic creatine kinase (CK) elevation to severe, disabling, HIV-associated polymyositis or pyomyositis (Table 113-4). HIV seroconversion also can coincide with myoglobinuria and acute myalgia, suggesting that myotropism for HIV may be present early in the infection.

### Myalgia and Fibromyalgia

One-third of HIV$^+$ outpatients report myalgias,[2,44] and 11% describe fibromyalgia.[45] Fibromyalgia is associated with longer disease duration and a history of depression. Treatment is similar to that for fibromyalgia in the non-HIV setting.

**TABLE 113-4** Myopathies Associated with HIV Infection

| HIV-Associated Myopathies | Myopathies Secondary to Anti-retrovirals | Others |

HAART, Highly active anti-retroviral therapy; NRTIs, nucleoside reverse transcriptase inhibitors.

### Non-inflammatory Necrotizing Myopathy and HIV-Related Wasting Syndrome

Severe wasting from chronic infection, malignancy, malabsorption, and nutritional deficiency often accounts for weakness and disability in patients with AIDS.[46] This wasting leads to loss of lean body and muscle mass. Cachexia and muscle wasting associated with HIV constitute "slim disease" in Africa. A non-inflammatory necrotizing myopathy of unclear pathogenesis has been described, accounting for 42% of patients diagnosed with myopathy.[45] Even in patients without significant wasting, muscle biopsy specimens have shown diffuse atrophy, mild neurogenic atrophy, or thick filament loss without conspicuous inflammation. Whether this condition is immune mediated, as some have suggested,[47] or whether it is the result of metabolic or nutritional factors remains unclear. Corticosteroids have been reported to restore muscle strength and mass.[47]

### Nemaline Myopathy

Nemaline myopathy is a rare disorder that has been described in some HIV$^+$ patients in addition to its occurrence as a congenital disorder. Nemaline myopathy represents a nonspecific myofibril alteration resulting from Z band disruption.[49] Muscle-biopsy specimens disclose prominent, randomly distributed, atrophic type 1 fibers with numerous intracytoplasmic rod bodies in the centers of the fibers, corresponding to nemaline rods at electron microscopy. Necrotic fibers and inflammatory infiltrates usually are not found. Some patients have been described to have associated monoclonal gammopathy.[48] Although no inflammation is noted, corticosteroids may be useful. In addition, two cases of successful treatment with intravenous immunoglobulin (IVIG) have been reported.[50]

### HIV-Associated Polymyositis

HIV-associated polymyositis most typically manifests early in the course of HIV infection and may be the presenting feature. In one large series of HIV$^+$ outpatients from a county clinic in Texas, the frequency was 2.2 per 1000.[51]

The pathogenesis of HIV-associated polymyositis is unclear—possibly stemming from direct viral invasion (leading to a cytopathic effect and subsequent muscle necrosis), as suggested in one pathologic study,[52] or from an autoimmune response of the HIV host, as suggested by another study.[53]

The most common manifestation is a subacute, progressive proximal muscle weakness occurring in the setting of an elevated CK. Myalgia is not a prominent presenting feature. Skin involvement is unusual, as is involvement of extra-ocular muscles and facial muscles. In a recent report from Africa, HIV polymyositis cases were all female and, compared to the non-HIV polymyositis cases, were younger and with fourfold lower serum CK.[54] On the other hand, only a handful of cases of dermatomyositis in HIV have been reported, usually in the setting of advanced immunodeficiency.[55] CK levels may be less elevated or even normal in some HIV-associated polymyositis patients.[51,54]

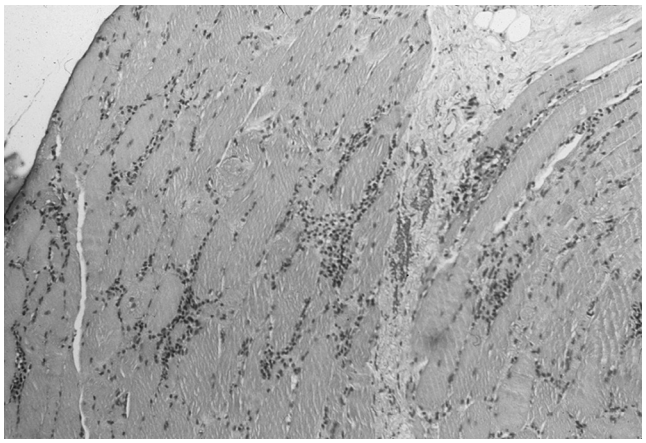

**Figure 113-4** Muscle biopsy specimen from a patient with HIV–associated polymyositis.

On MRI, T2-weighted studies with or without fat saturation show high signal intensity without rim enhancement, in contrast to pyomyositis, in which rim enhancement is seen.[56] MRI also is helpful in guiding muscle biopsy—the definitive diagnostic test. Electromyographic studies reveal myopathic motor unit potentials with early recruitment and full interference patterns and fibrillation potentials, positive sharp waves, and complex repetitive discharges indicative of an irritative process. Light microscopy of muscle biopsy specimens shows interstitial inflammatory infiltrates of variable intensity accompanied by degenerating and regenerating myofibrils, similar to those seen in polymyositis without HIV (Figure 113-4). Concomitant vasculitis rarely occurs. In specimens from $HIV^+$ and $HIV^-$ patients with myositis, the predominant cell populations were $CD8^+$ T cells and macrophages invading or surrounding healthy muscle fibers that express class I major histocompatibility complex (MHC) antigens on their cell surfaces.[57] Endomysial infiltrates in specimens from $HIV^+$ patients differed from those of patients with polymyositis without HIV infection only by a significant reduction of $CD4^+$ cells.[53]

Treatment is similar to that provided for other inflammatory myopathies. CK elevation and muscle weakness respond to moderate-dose glucocorticoids.[51,54] Refractory cases may require immunosuppressive agents, such as methotrexate, azathioprine, or mycophenolate mofetil. IVIG has been used with some success. These agents should be used with caution, however, with careful monitoring of the patient's clinical status, $CD4^+$ counts, and HIV mRNA levels.

CK elevation is commonly encountered in outpatients with HIV infection, secondary to HIV per se, behaviors associated with higher risk for HIV infection (e.g., cocaine use), or HIV treatment.[51] In most patients, these elevations are transient and are of little consequence, but they require careful follow-up for any sign of clinical deterioration before electrodiagnostic and biopsy studies are undertaken.

## Inclusion Body Myositis

Inclusion body myositis has been recognized as a complication of HIV infection.[58] This condition is clinically, histologically, and immunologically identical to sporadic inclusion body myositis. Muscle biopsy specimens suggest two concurrently ongoing processes—an autoimmune process mediated by cytotoxic T cells and a degenerative process manifested by vacuolated muscle fibers and deposits of amyloid-related proteins. Of particular interest has been the finding of elevated mRNA levels and constitutive expression of Toll-like receptor 3, which is known to mediate inflammatory stimuli from pathogens and endogenous danger signals, and to link the innate and adaptive immune systems, in muscle fibers of patients with HIV-associated inclusion body myositis in close proximity with infiltrating mononuclear cells.[59] One review of four cases of HIV-associated inclusion body myositis found that involved $CD8^+$ cells surrounding muscle fibers were virus-specific and may cross-react with antigens on the surface of muscle fibers, suggesting that HIV may trigger a viral-specific inflammatory response that can lead to inclusion body myositis.[60]

## Myopathy Associated with Treatment

A reversible toxic mitochondrial myopathy occurring in patients who received high doses of zidovudine has been described, which manifests as myalgias, muscle tenderness, and proximal muscle weakness mimicking HIV polymyositis.[61] Reports have also described mitochondrial toxicity manifesting as ptosis or ophthalmoplegia in $HIV^+$ patients on zidovudine and other nucleoside reverse transcriptase inhibitors (NRTIs) such as didanosine.[62,63] Histologically, it is characterized by the presence of *ragged red fibers*, a term coined to designate atrophic ragged red fibers with marked myofibril alterations, including thick myofilament loss and cytoplasmic body formation,[64] and minimal inflammatory infiltrates. Symptoms tend to improve while the drug is discontinued, with CK levels returning to normal within 4 weeks of discontinuing the drug and muscle strength returning within 8 weeks. In any HIV-infected patient seen with an elevated CK level, especially when symptoms of myalgia or muscle weakness are present, zidovudine should be discontinued for 4 weeks and the patient re-evaluated before electromyography or muscle biopsies are undertaken. However, with decreasing use of zidovudine and new medications, other myopathic complications are being seen. The use of raltegravir is associated with a higher prevalence of symptomatic skeletal muscle toxicity, which does not seem to be concentration or time dependent, nor associated with elevated CK. Proximal myopathy may be an uncommon but significant side effect of raltegravir exposure.[65]

## Rhabdomyolysis

Rhabdomyolysis can occur at all stages of HIV infection and may be separated into three groups: (1) HIV-associated rhabdomyolysis, including rhabdomyolysis in primary HIV infection, recurrent rhabdomyolysis, and isolated rhabdomyolysis; (2) drug-induced rhabdomyolysis; and (3) rhabdomyolysis at the end stage of AIDS, associated or not with opportunistic infection of muscle. Drugs implicated in rhabdomyolysis in HIV patients include didanosine, lamivudine, trimethoprim-sulfamethoxazole, ritonavir, indinavir, and raltegravir.[64,66]

## DIFFUSE INFILTRATIVE LYMPHOCYTOSIS SYNDROME

Diffuse infiltrative lymphocytosis syndrome (DILS), found exclusively in $HIV^+$ patients, is characterized by salivary gland enlargement and peripheral $CD8^+$ lymphocytosis often accompanied by sicca symptoms and other extraglandular features. The prevalence of DILS is declining since the introduction of HAART.[67] Using parotid enlargement as a criterion, the prevalence in Houston, Texas, was 4% in the pre-HAART era, declining to 0.8% after the introduction of aggressive HIV therapy.[67,68] In another study from Greece, using xerophthalmia and xerostomia as the defining criteria (and requiring confirmatory minor salivary gland biopsy specimen and technetium scintigraphy),[69] the prevalence of DILS was 7.8% and has decreased dramatically there and elsewhere after the introduction of HAART.[2,67,70]

The primary immunogenetic association has been with HLA-DRB1 alleles expressing the ILEDE amino acid sequence in the third diversity region—usually HLA-DRB1*11:02, DRB1*13:01, and DRB1*13:02.[67,71] Delayed progression to AIDS in patients with DILS has been attributed to delay in the evolution of HIV from the less aggressive M-tropic strain to the more rapidly replicating T-tropic strain by a more effective $CD8^+$ lymphocyte response.[72] This response has been attributed in part to the finding of sequence homology of a six-residue epitope shared by HLA-DRB1 alleles associated with DILS with a V3 loop on M-tropic HIV strains. Studies of immunophenotypes of circulating and tissue-infiltrating lymphocytes and salivary gland T cell-receptor sequence analysis suggested that DILS represents an MHC-restricted, antigen-driven, oligoclonal selection of $CD8^+$, $CD29^-$ lymphocytes that express selective homing receptors and infiltrate the salivary glands, lungs, and other organs, where they are postulated to suppress HIV replication.[72]

Minor salivary gland biopsy specimens show a focal sialadenitis, similar to that observed in Sjögren's syndrome, although destruction of the salivary glands tends to be lessened (Figure 113-5). $CD8^+$ lymphocytes constitute most of the inflammatory infiltrate,[73,74] in contrast to that seen in primary (non–HIV-associated) Sjögren's syndrome. Lymphoepithelial cysts are seen frequently in the parotid glands of patients with DILS, leading to inspissated salivary secretions that may be painful.

The characteristic, if not defining, presentation of DILS consists of painless parotid enlargement, often massive (Figure 113-6). This enlargement is accompanied by sicca symptoms in more than 60% of patients. Although parotid and submandibular enlargement is nearly universal in this disorder, certain extraglandular features also are prominent (Table 113-5). DILS and Sjögren's syndrome share some similarities and differences (Table 113-6).

Diagnostic criteria have been proposed for DILS as follows:

- HIV seropositive by enzyme-linked immunosorbent assay and Western blot analysis.
- Bilateral salivary gland enlargement or xerostomia persisting for longer than 6 months.
- Histologic confirmation of salivary or lacrimal gland lymphocytic infiltration in the absence of granulomatous or neoplastic enlargement.

Minor salivary gland biopsy specimens are usually positive (see Figure 113-5). Gallium-67 scintigraphy (Figure 113-7) of the salivary glands has been used when lip biopsy was not feasible or equivocal. Tc99m pertechnetate scanning offers little diagnostic help. Scintigraphy is used as a primary diagnostic aid in patients on protease inhibitors because minor salivary gland biopsy specimens are rarely positive in patients on these drugs. CT also has been used to determine the extent of glandular swelling and to evaluate parotid cysts and possible salivary glandular malignancy.

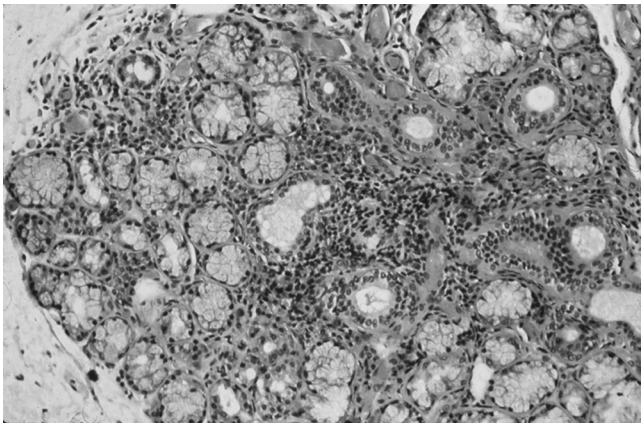

**Figure 113-5** Minor salivary gland biopsy specimen from a patient with diffuse infiltrative lymphocytosis syndrome. Note the relative preservation of the glandular architecture, even with significant interstitial inflammation.

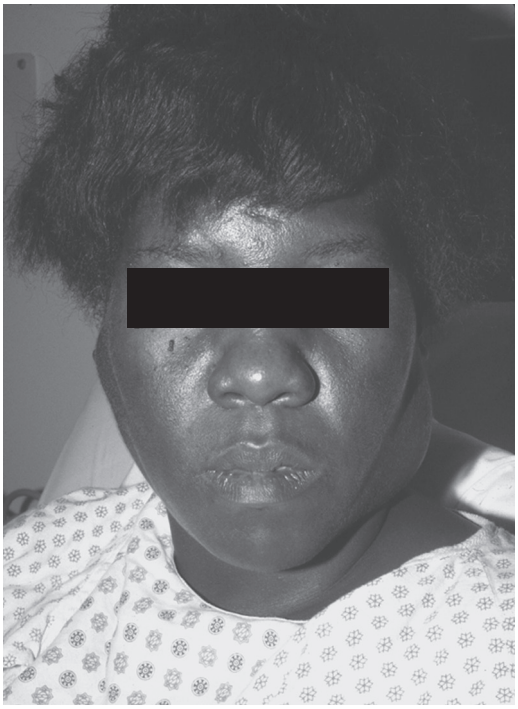

**Figure 113-6** Massive bilateral asymmetric salivary gland enlargement in a patient with diffuse infiltrative lymphocytosis syndrome. This was the presenting feature of human immunodeficiency virus infection in this patient. Computed tomography revealed this to be a solid mass. At follow-up 2 years after this photograph was taken, the gland had not changed in size.

| Drainage and instillation of corticosteroids into parotid lymphoepithelial cysts |
| Radiation of parotid cysts |

**Figure 113-8** Aspiration of a parotid epithelial cyst in a patient with diffuse infiltrative lymphocytosis syndrome.

Patients with asymptomatic glandular swelling and mild, if any, sicca symptoms can be observed over time (Table 113-7). Anti-retroviral treatment is effective in treating the glandular swelling and sicca symptoms associated with DILS and complications such as neuropathy.[67] We have found also that moderate doses of corticosteroids (30 to 40 mg/day of prednisone) are effective in treating the glandular swelling and sicca symptoms of DILS without adversely affecting the frequency of opportunistic infections, increasing the viral loads, or depressing the $CD4^+$ counts, although the effect is transient. Lymphocytic interstitial pneumonitis may require higher doses of corticosteroids (60 mg/day of prednisone), sometimes for extended periods. Radiation therapy should be avoided. Cranial nerve VII palsy tends to respond poorly to any treatment. Combination anti-retroviral therapy has been reported to be effective in resolving parotid epithelial cysts, although when refractory, the cysts can be managed by aspiration and instillation of 1 mL (40 mg) of either methylprednisolone or triamcinolone suspension into the cyst (Figure 113-8). Frequent recurrence may necessitate surgical excision.

## VASCULITIS ASSOCIATED WITH HIV INFECTION

A wide spectrum of vasculitis has been described in patients with HIV infection.[75,76] Fever, malaise, weakness, rash,

headaches, and neurologic symptoms are common in HIV$^+$ patients, and triggers of vasculitis range from specific infectious agents and drugs to idiopathic causes. Among infectious causes, cytomegalovirus and tuberculosis are probably the most common. Inflammatory vasculitides are less common rheumatologic diseases that occur in less than 1% of HIV patients.

One series found 34 (23%) of 148 "symptomatic" HIV$^+$ patients to have vasculitis.[77] Of these patients, 11 met American College of Rheumatology criteria for a distinct category of vasculitis, including hypersensitivity vasculitis in 6, polyarteritis nodosa in 4, and Henoch-Schönlein purpura in 1. Another series of 98 Chinese patients found that 20% had vasculitis, including 15 with Behçet's-like disease, 2 cases of Henoch-Schönlein purpura, 2 cases of digital gangrene, and 1 case of CNS vasculitis.[78] Granulomatosis with polyangiitis and pulmonary microscopic polyangiitis can occur in patients with high CD4$^+$ counts and during immune reconstitution. Eosinophilic granulomatosis with polyangiitis (Churg-Strauss Syndrome) has also been described.[79] Behçet's disease and relapsing polychondritis occur in HIV infection[79,80] and respond to HAART.[81]

Rapidly progressive focal necrotizing vasculitis of the aorta and large arteries with occlusion and occasionally aneurysm formation and rupture has been described in Africans with HIV infection. In one recent study, 90% of HIV$^+$ patients, but no HIV$^-$ patient, had evidence of adventitial leukocytoclastic vasculitis of the vasa vasorum.[82] Giant cell arteritis likewise has been described in patients with HIV infection with aortic root dilation.[83] Kawasaki's disease has been reported in HIV$^+$ children and adults.[84] Cryoglobulinemic vasculitis with associated lymphocytic interstitial pneumonia occurs with and without hepatitis C coinfection.

Patients with isolated CNS angiitis usually are seen with organic brain syndromes and neurologic deficit.[85] In children and in one case report in an adult, HIV-associated cerebral aneurysmal arteriopathy was described as causing multiple fusiform aneurysms in the circle of Willis.[86] CNS vasculitis may manifest as recurrent strokes. Although imaging studies (MRI, angiography) may be helpful, brain biopsy may be necessary to establish the diagnosis. Necrotizing granulomatous vasculitis not limited to the CNS has been reported in patients with low CD4$^+$ counts that respond to anti-retroviral therapy.[75] More recently, a case report has described leukocytoclastic cerebral vasculitis treated with anti-CD25 antibody.[87]

Diagnosis is based on a high degree of suspicion and on angiography and biopsy of specific organ beds. Similar to immunocompetent patients, perinuclear anti-neutrophil cytoplasmic antigen (pANCA) and cytoplasmic anti-neutrophil cytoplasmic antigen (cANCA) may be useful with granulomatosis with polyangiitis or microscopic polyangiitis. However, biopsy with cultures is important to rule out infectious mimics.

Corticosteroids are the mainstay of treatment for HIV-associated vasculitis, although cytotoxic agents such as cyclophosphamide, IVIG, and plasmapheresis have been used in refractory cases. Painful neuropathy secondary to vasculitis responds well to high-dose glucocorticoids, in contrast to HIV-associated peripheral neuropathy.[87,88]

## PRIMARY PULMONARY HYPERTENSION

Pulmonary hypertension is a severe life-limiting disease that often affects younger patients. Patients with AIDS and primary pulmonary hypertension present with a higher degree of pulmonary hypertension than non-AIDS patients.[89,90] The predominant histopathologic finding has been a plexogenic pulmonary arteriopathy, although thromboembolic changes also have been reported. One group found an association with HLA-DRB1*13:01 and HLA-DRB1*13:02 and with the linked allele HLA-DRB3*03:01.[90]

Symptoms include progressive shortness of breath, pedal edema, nonproductive cough, fatigue, syncope or near-syncope, and chest pain. Pulmonary function tests show mild restrictive patterns with variably reduced diffusing capacities. In a review of 131 cases of pulmonary hypertension associated with HIV infection, the interval between the diagnosis of HIV disease and the diagnosis of pulmonary hypertension was 33 months. The median length of time from diagnosis to death was 6 months.[91] However, with improving treatment of pulmonary hypertension, the prognosis has improved considerably. Responses to vasodilator agents—calcium-channel blockers, sildenafil, intravenous and inhaled prostanoids, and endothelin antagonists—and to HAART vary, and recent studies show improved mortality.[92,93]

## HIV-ASSOCIATED MUSCULOSKELETAL INFECTION

### Pyomyositis

Pyomyositis is a primary infection of skeletal muscle that does not arise from contiguous infection; it is presumably hematogenous in origin and often is associated with abscess formation. Rarely seen in developed countries, infectious myositis nonetheless is an important complication of HIV infection in areas most endemic for HIV, such as Africa and India. It tends to occur in later stages of the infection, with CD4$^+$ counts less than 200/μL. *Staphylococcus aureus* is the most common pathogen.[94] Other organisms that have been implicated include *Streptococcus pyogenes*, *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, *Mycobacterium avium-intra-cellulare*, *Nocardia asteroides*, *Salmonella enteritidis*, *Escherichia coli*, *Citrobacter freundii*, *Morganella morganii*, *Pseudomonas aeruginosa*, and group A streptococci.

The clinical course of pyomyositis can be roughly divided into three stages: invasive, suppurative, and late. The first stage, which typically lasts 1 to 3 weeks, is characterized by localized cramplike pain and induration in conjunction with a low-grade fever. Large muscle groups, particularly those of the lower extremities, are most often affected. The degrees of pain and fever increase in the second stage, which is characterized further by the development of edema and pus in the affected muscle. Untreated, the disease progresses to the third stage; within 3 weeks of onset, sepsis and death can occur.[95] The mortality rate associated with pyomyositis has been estimated to range from 1% to 20%. Ultrasound and MRI with contrast enhancement are effective in localizing infection, although sometimes tagged

white blood cell scans may be needed. Oral and intravenous antibiotics in conjunction with surgical drainage are often required.

## Bacterial Arthritis and Osteomyelitis

No data suggest that bacterial infection of bones or joints occurs more frequently in patients with HIV infection.[96] *S. aureus* is the most common infectious agent encountered, but parenteral drug use and not HIV infection per se may account for this. Many other organisms have been reported to cause osteomyelitis in HIV-infected patients, including *Mycobacterium tuberculosis*, *Salmonella*, *Nocardia asteroides*, *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, cytomegalovirus, invasive *Aspergillus*, *Toxoplasma gondii*, *Torulopsis glabrata*, *Cryptococcus neoformans*, and *Coccidioides immitis*. Osteomyelitis is associated with mortality rates of greater than 20% in HIV-infected patients. The most frequently involved bones are the wrist, tibia, femoral heads, and thoracic cage, but other rare sites, such as the patella and the mandible, have been reported.

## Musculoskeletal Tuberculosis

Musculoskeletal involvement, the fourth most common extrapulmonary manifestation of tuberculosis, is found in approximately 1% to 5% of patients with tuberculosis. It can mimic many skeletal diseases and can manifest in various locations. Less than 50% of reported patients with musculoskeletal tuberculosis have radiographic evidence of pulmonary tuberculosis. *M. tuberculosis* disseminates hematogenously after an acute or reactivated pulmonary infection. Usually, skeletal tuberculosis lesions in immunocompetent patients are solitary, but in AIDS patients, they may have a multicentric distribution in approximately 30% of cases.[95] The vertebrae are the most common site involved, mostly the lower thoracic or upper lumbar segments. The frequency of tuberculous spondylitis is 50% to 66%; peripheral arthritis, 20% to 30%; osteomyelitis, 10% to 20%; and tenosynovitis and bursitis, approximately 1% to 3%. Treatment includes four-drug antitubercular therapy and, often, surgical intervention.

## Atypical Mycobacterial Infection

Musculoskeletal infection caused by atypical mycobacterial species is unusual in immunocompetent individuals.[97] Atypical mycobacterial species most commonly implicated in causing septic arthritis or osteomyelitis in HIV include *M. avium-intra-cellulare* complex, *Mycobacterium kansasii*, *Mycobacterium haemophilum*, *Mycobacterium terrae*, and *Mycobacterium fortuitum*. *M. haemophilum* has been most frequently implicated in skeletal infection, accounting for more than half of cases, and *M. kansasii* is second, accounting for an additional 25%. These are systemic infections that have involved several joints or skeletal sites. Cutaneous lesions, such as nodules, ulcers, and draining sinus tracts, occur in approximately 50% of patients.[97] These infections tend to occur late in the course of HIV, usually when the $CD4^+$ T lymphocyte count is less than 100/μL. *M. avium-intra-cellulare* complex osteomyelitis has also been associated with immune reconstitution inflammatory syndrome after initiation of HAART.[98] Along with standard antituberculosis therapy, clarithromycin is effective.[97]

## Bacillary Angiomatosis Osteomyelitis

Bacillary angiomatosis is a multisystem infectious disease caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. It seems to be a disease unique to HIV-infected patients and, to a lesser degree, to other immunocompromised patients.[99] Clinical characteristics associated with bacillary angiomatosis and bacillary peliosis (BAP) in patients with HIV infection include fever (temperature, >37.8° C; 93%), cutaneous or subcutaneous vascular lesions, lymphadenopathy, osteomyelitis, and abdominal symptoms associated with profound depression of CD4 lymphocyte counts, anemia, and elevated serum level of alkaline phosphatase.[99,100]

Osteomyelitis is found in approximately one-third of patients in association with skin disease. These lesions usually are characterized by extensive destruction of the cortical bone, periostitis, medullary invasion, and an overlying soft-tissue mass that might resemble cellulitis. Complete remission of bacillary angiomatosis after doxycycline or erythromycin therapy occurs, although bone lesions may need surgical drainage.

## Fungal Infections

In addition to bacterial infection, patients with advanced HIV infection ($CD4^+$ T lymphocyte count <100/μL) are at high risk for fungal musculoskeletal infections, particularly infections caused by *Candida albicans*[101] and *Sporothrix schenckii*.[102] *S. schenckii* can manifest with oligoarticular or even polyarticular involvement and tenosynovitis (Figure 113-9) and can be particularly difficult to eradicate, requiring long-term suppressive antifungal therapy. Various disseminated fungal infections, such as histoplasmosis, cryptococcosis, and blastomycosis, occur in HIV and often cause osteomyelitis.

## Parasitic Infections

Muscle toxoplasmosis is found in profoundly immunodepressed patients, typically manifesting with a painful subacute myopathy and concurrent multivisceral toxoplasmosis.[103] *Toxoplasma* cysts are observed mainly in muscle fibers in muscle biopsy specimens, and identification of cysts as *Toxoplasma* may be easier when specific antibodies or electron microscopy is used. Muscle weakness such as in polymyositis can occur in muscle toxoplasmosis. Treatment is based on a combination of drugs acting synergistically against *T. gondii*, including pyrimethamine and sulfadiazine or trisulfapyrimidines.

# RESPONSE OF OTHER RHEUMATIC DISEASES TO HIV INFECTION

Early reports suggest that rheumatoid arthritis went into remission in the face of HIV infection. Early reports likewise suggest that HIV infection might reduce the activity of systemic lupus erythematosus, particularly at times of low $CD4^+$ T cell counts. With emergence of the immune

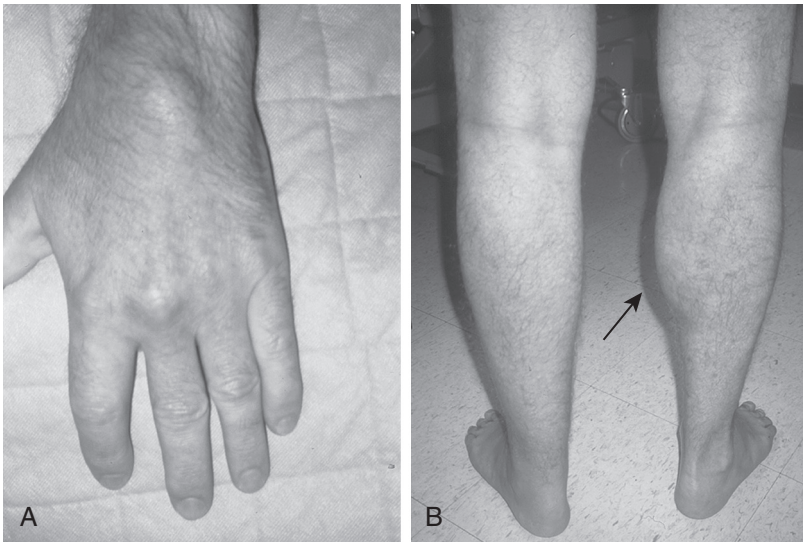

**Figure 113-9** **A,** Third metacarpophalangeal synovitis and common extensor digitorum longus tendon sheath effusion at the dorsal surface of the wrist. **B,** Dissecting Baker's cyst *(arrow)* in the same patient with disseminated *Sporothrix schenckii* infection (organism cultured from synovial fluid obtained from both sites).

reconstitution syndrome, most autoimmune diseases appear de novo or recur with institution of HAART and increased $CD4^+$ counts.[7,104]

## HAART-RELATED IMMUNE RECONSTITUTION SYNDROME

Starting HAART may be initially accompanied by aberrant inflammatory responses termed immune reconstitution inflammatory syndrome (IRIS), wherein patients experience paradoxical deterioration in response to HAART, despite efficient control of HIV viral replication and no apparent drug toxicity.[105,106] It was initially described with recrudescence of infections, but now autoinflammatory and autoimmune phenomena are being described. A meta-analysis of more than 13,000 HIV patients starting HAART found that IRIS developed in 13%.[107] The mean time of onset of IRIS from the time of HAART initiation is approximately 9 months.[107]

Shelburne and co-workers[105] put forth four criteria required for the diagnosis of immune reconstitution inflammatory syndrome, as follows:

1. Patient has been diagnosed with AIDS.
2. Treatment with anti-HIV therapy results in increased $CD4^+$ counts and decreased HIV viral load.
3. Infectious and inflammatory symptoms appear during therapy.
4. Symptoms cannot be explained by a new cause.

Improved understanding of the immunology of IRIS has helped elucidate how atypical, hyperaccentuated inflammatory host responses to pre-existing or co-existing infection can occur in HIV patients taking HAART. HIV infection causes a relentless decline in $CD4^+$ memory and naïve cells, an increase in activated T cells in the peripheral blood, and thymic dysfunction. HAART can lead to sustained suppression of HIV and concomitant repopulation of T cell counts in a biphasic mode.[107] The first phase represents the release of predominantly memory $CD4^+$ cells and lasts a few weeks to months. The second phase, from approximately 6 months on, represents the main phase of naïve T cell proliferation and is accompanied by changes in T helper cytokine production profiles.[108,109] IRIS can occur during both phases of immune recovery, and different infections and autoimmune phenomena occur in phase 1 compared with phase 2.

Organ-specific autoimmune phenomena have been described more often than generalized systemic autoimmune disease and tend to occur later during reconstitution. These phenomena may be a manifestation of naïve T cell release as opposed to memory T cell reconstitution. Graves' thyroiditis occurring approximately 21 months after initiation of HAART has been described in approximately 17 cases.[110] Terminal ileitis, alopecia universalis, cerebral $CD8^+$ lymphocytosis, and Guillain-Barré syndrome[111] have been reported. Polymyositis,[112] rheumatoid arthritis,[7] systemic lupus erythematosus,[113] autoimmune hepatitis, adult Still's disease, and sarcoidosis[114] newly appearing after initiation of HAART also have been described. These conditions tend to occur earlier during reconstitution compared with organ-specific autoimmunity. In addition, IRIS has been reported in the setting of TNF blocker discontinuation, with cryptococcal pneumonia occurring in an $HIV^+$ patient after stopping adalimumab.[115]

If a diagnosis of IRIS is made, HAART is continued, and most symptoms resolve with little or no therapy. If inflammatory symptoms involve areas where significant damage secondary to uncontrolled inflammation is likely to occur, such as in the CNS or eye, HAART should be stopped, and careful use of corticosteroids should be considered. IRIS is less likely to occur if the $CD4^+$ count is greater than 200/μL when HAART is initiated.[106,107] Other risk factors for IRIS include being HAART naïve and the presence of a high antigenic burden with opportunistic infection when HAART is begun.[115,116] Continued systematic analysis is needed, however, and guidelines need to be established for

defining the autoimmunity associated with immune reconstitution. The prognosis for most IRIS cases is favorable because a robust inflammatory response may predict an excellent response to HAART in terms of immune reconstitution and, perhaps, improved survival.

## RHEUMATOLOGIC COMPLICATIONS OF HIV TREATMENT

The myopathy associated with nucleoside transcriptase inhibitors such as zidovudine and the osteonecrosis and parotid lipomatosis associated with the use of protease inhibitors have been discussed previously. In addition to these conditions, cases of adhesive capsulitis, Dupuytren's contracture, tenosynovitis, and temporomandibular joint dysfunction have been reported as a consequence of indinavir treatment.[116]

## LABORATORY ABNORMALITIES ASSOCIATED WITH HIV INFECTION

Humoral immunologic abnormalities are frequent in patients with HIV but are rarely associated with severe clinical signs. The most common laboratory abnormality is polyclonal hyperglobulinemia, found in 45% of HIV$^+$ individuals.[117] Rheumatoid factor and anti-nuclear antibodies, usually in low titer, have been described in 17% of patients with HIV infection in some series,[117,118] although anti-dsDNA antibodies and hypocomplementemia are rare. Increased titers of anti-citrullinated protein antibody (ACPA) and rheumatoid factor occur in advanced HIV infection. Although more specific than rheumatoid factor, before immune reconstitution, ACPA is an unreliable diagnostic marker for RA and does not necessarily predict future RA. Immunoglobulin (Ig)G anti-cardiolipin antibodies are found in 95% of untreated patients with AIDS, particularly in patients with advanced disease, and overall in 20% to 30% of HIV$^+$ individuals.[119] They are rarely associated with thrombotic events. cANCAs and pANCAs have been described in the serum of HIV$^+$ individuals, as have anti–glomerular basement membrane antibodies.[120] Cryoglobulinemia is decreasing in this population since the introduction of HAART.[121] Indeed, with HAART, many of these serologic abnormalities tend to decrease or resolve.

## CONCLUSION

The impact of the global HIV pandemic continues to grow, and rheumatologists need to be aware of the wide spectrum of rheumatic diseases that occur in HIV$^+$ patients. HAART has changed the natural history of HIV infection. It has modified the frequency and expression of some HIV-related clinical syndromes and has been associated directly (toxicity) and indirectly (immune reconstitution) with the development of new ones. With longer survival and newer refinements in treatment, the spectrum of rheumatic disease seen in HIV$^+$ patients is very much a moving target for rheumatologists and is likely to continue to evolve.

CHAPTER 114

# Viral Arthritis

Philippe Gasque

**KEY POINTS**

- Viral infection can lead to chronic arthralgia and symmetric polyarthritis, particularly in elderly patients.
- Exposure, travel, occupation, and vaccination histories should be considered.
- Parvovirus B19 is one of the most common viral arthritides.
- Rubella arthritis can occur in young adults. Rubella vaccination has reduced the overall incidence of infection but can provoke arthritis.
- Alphaviruses are African/Asian mosquito-borne causes of arthritis and rash. Outbreaks are emerging worldwide (including in Europe, the Caribbean islands, and the United States). For example, Chikungunya can cause chronic arthralgias evolving to arthritis, months to years postinfection and in more than 50% of adult patients.
- Hepatitis C virus, Epstein-Barr virus, and many other viruses that find sanctuaries in synovial tissues can cause arthritis.
- Robust humoral and cellular anti-viral responses may not control for viral persistence. Viruses can interfere with the innate immune response.
- Nonconventional autoimmune responses may orchestrate arthritis. Anti-citrullinated antibodies are rare.
- Synovial macrophages and fibroblast-like synoviocytes that carry viral remnants orchestrate the inflammatory response and are associated with angiogenesis and cell hyperplasia.
- NSAIDs, methotrexate, and preventive vaccination measures are beneficial

Many viruses have been claimed to be commonly associated with arthritogenic diseases and reminiscent of rheumatoid arthritis (RA): old world alphaviruses such as Chikungunya (CHIKV) and Ross river virus (RRV)[1-5] and, more rarely, parvovirus B19, Epstein-Barr virus (EBV), rubella, and hepatitis B/C virus (HBV/HCV)[6-9] (Table 114-1). Other viruses such as adenoviruses, coxsackie viruses, HIV, influenza, measles, mumps, and varicella zoster are more likely to be linked to autoimmune responses such as type I diabetes, and may also affect the joints, leading to reactive arthritis.[1,10]

The phenotypes of these diseases may be distinct in terms of the primary cells and tissues initially targeted, the specific humoral and cellular immune responses elaborated, and the inflammatory effector pathways that predominate. Despite the different nature of each viral disease, however, they clearly share some common pathogenic mechanisms involved in arthralgias (acute nociception at the nerve endings), macrophage activation and polarization, as well as fibroblast hyperplasia and invasion sustained by major angiogenesis in the synovial tissues as described in RA (Figure 114-1).[11-13]

Early and robust systemic innate and adaptive immune anti-viral responses are important events to protect the host, including the contribution of the epithelia, a major portal of entry for many of these viruses at the lung and skin.[14] However, in the context of a major infection associated with high viremia and a failure to mount a robust anti-viral response, it has been proposed that the virus would escape from immune surveillance and find protective niches in tissues such as synovial tissues.[12] Indeed, the acute virus infection might, in a genetically predisposed or otherwise susceptible host (e.g., association with human leukocyte antigen [HLA] or immune senescence in elderly patients), be able to recapitulate a polarized inflammatory response as described in RA and other autoimmune diseases.[15] Viruses could also polarize host-cell defense mechanisms such as type I interferon (IFN) signaling pathways, apoptosis, and autophagy to its own advantage.[16,17]

As discussed below, it is increasingly recognized that synovial tissue is a sanctuary for many arthritogenic viruses, which can recruit reactive T and, more rarely, B cells to the joints to drive chronic inflammation and, ultimately, contribute to hyperplastic synovial pannus tissue formation, and finally to the destruction of cartilage and bone as found in RA.[13,18] Viruses could be brought into the synovial tissue by infected monocytes, fibrocytes, or lymphocytes before being transferred to resident cells such as synovial fibroblasts.[12,19,20]

Autoimmunity against self-antigens prominently expressed by infected synovial fibroblasts may be exceptionally engaged through bystander activation and the expression of cryptic antigens and more rarely through well-described molecular mimicry mechanisms.[10]

Surprisingly, many of the self-antigens are nuclear or mitochondrial proteins released by dying cells as a consequence of the infection but which are also critically involved as natural adjuvants (also called *alarmins*) to alert innate and adaptive immune cells.[21,22,22]

Paradoxically, the events involved in the clearance of viruses will contribute to sustained chronic inflammation and will instigate arthralgia and ultimately leading to destructive arthritis. Regulatory mechanisms to control chronic inflammation have been recently emphasized, but

**TABLE 114-1** Examples of Viruses Implicated in Human Chronic Arthralgia and Arthritis

| | PRIMARY INFECTION (PI) AND ACUTE RESPONSES | | CHRONIC RESPONSES (MONTHS TO YEARS AFTER PI) AND FACTORS THAT MAY BE INVOLVED | | | | |
|---|---|---|---|---|---|---|---|
| **Virus (Clinical Hallmarks)** | **Primary Target Cells** | **Cellular and Humoral Immunity Against Virus** | **Tissue Sanctuaries** | **Systemic, Synovial Tissues and Articular Chronic Inflammations/ Injuries** | **Chronic Arthralgia** | **Humoral/Cellular Autoimmune and Inflammatory Responses** | **Therapies of Arthralgia and Arthritis** |
| **RNA Viruses** | | | | | | | |
| CHIKV (Arthralgia) (Myalgia) (Tenosynovitis) | Fibroblast (skin)[16,55,76] Receptor-mediated entry is unknown | Robust activation of NK cells[107] Robust activation of T/B immunity against virus[107] Poor expression of type I IFN by dendritic cells[76] Monocytes can be infected[73] and carry the virus to sanctuary | Localization of virus (RNA, proteins) in synovial perivascular macrophages and few fibroblasts months after infection in one patient[107] and in nonhuman primates[71] and in mouse model[57] Ballooned macrophage NK cells, T cells, but no PMN, are found in synovial fluids as in RRV patients | High levels of interferon type I (alpha) High levels of Apoptosis in synovium Complement activation and cytotoxicity may be involved[141] High levels of angiogenesis in synovium and may assist fibroblast aggressive phenotype (proliferation and invasion)[107] | May be associated with high levels of COX2 CHIKV-induced high levels of PGE2 by fibroblasts[138] Roles of other molecules involved in pain remain unknown (NGF, Substance P, kinins, anaphylatoxins[133] | Canonical anti-citrullinated antibodies are rare. CHIKV-infected osteoblast and fibroblasts promote osteoclast differentiation through RANKL and possibly to joint damage[146] | Antalgics NSAIDs Methotrexate[24] TNF inhibitors CCL2 inhibitors[149] |
| **DNA Viruses** | | | | | | | |
| Parvovirus B19 (Anemia) (Arthralgia) | Precursors of red blood cell P glycoprotein and other coreceptors ($\alpha 5\beta 1$ and Ku80 nuclear antigen) | Robust activation of adaptive immunity against virus[8,34] Antibody specificity against some viral proteins may be compromised and favoring viral persistence[33] | Detection of viral DNA in synovial tissue of patients with RA[38] B and T cells are carriers of the virus to joints | In vitro, B19 can increase the invasive phenotype of fibroblast through poorly-characterized mechanisms[42] | Experienced by patients through unknown mechanisms | Molecular mimicry between viral proteins and proteins of the extra-cellular matrix (e.g., type II collagen)[40] Autoantibodies to nuclear, mitochondria and smooth muscle actin[39] | Methotrexate |

CHIKV, Chikungunya; IFN, interferon; NGF, nerve growth factor; NK, natural killer; PGE, prostaglandin; PMN, poly-morpho-nuclear cells (or neutrophils); RA, rheumatoid arthritis; RANKL, receptor activator of nuclear factor ligand; RRV, Ross river virus.

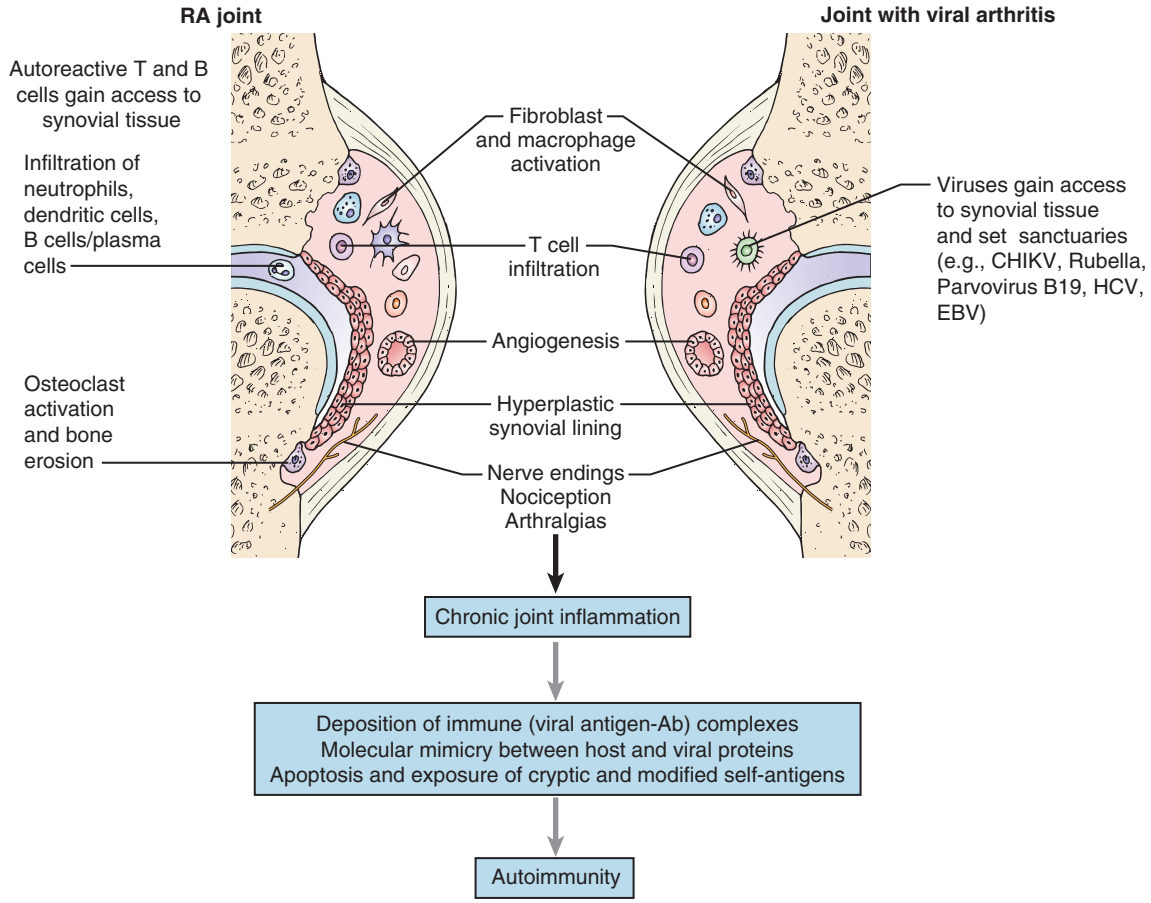

**Figure 114-1** Common and unique inflammatory pathways are involved in viral arthritis and reminiscent of autoimmune rheumatoid arthritis (RA). In the context of a major infection associated with high viremia and a failure to mount a robust anti-viral response, it has been proposed that several DNA and RNA viruses would escape from systemic immune surveillance and find protective niches in tissues such as synovial tissues. Infected monocytes, fibrocytes, or lymphocytes may transfer these viruses to resident cells such as synovial fibroblasts and perivascular macrophages but through ill-characterized mechanisms. Viruses may hide into apoptotic vesicles, allowing a Trojan horse–like scenario to subvert and infect resident cells. Despite the different nature of each viral disease, however, they clearly share some common pathogenic mechanisms involved in arthralgias (acute nociception at the nerve endings and involving for instance prostaglandins), macrophage activation and polarization (M2≫M1), as well as fibroblast hyperplasia and invasion sustained by major angiogenesis in the synovial tissues as described in RA. The T and B lymphocyte cell responses may help to thwart off viral challenge and persistence but could also contribute to bystander cell injuries. Dying resident cells may release cryptic and modified self-antigens, such as nuclear proteins or extra-cellular cell matrix (ECM) proteins (e.g., collagen, vimentin) which, in some individuals, may instigate a local autoimmune response. In RA and, to a much lesser extent, in viral arthritis, there is a major recruitment of neutrophils (releasing peptidyl arginine deiminase enzyme [PAD]), plasma cells, and dendritic cells, which will orchestrate a more robust autoimmune response characterized by antibodies against citrullinated proteins. Osteoclasts are involved in bone erosion. EBV, Epstein-Barr virus; HCV, hepatitis C virus.

little is known about their contributions in synovial tissues and whether or not they could favor viral persistence and chronic arthritis.[23]

The prevention measures should include vaccinations whenever possible in endemic regions, and particularly for vulnerable individuals such as the elderly. Other treatment regimens include analgesics and NSAIDs for pain relief and methotrexate (MTX) to control actual arthritis, although this may compromise patients' immune surveillance to prevent viral reactivation.[24,25]

This chapter describes key examples of some of the major DNA and RNA viruses associated with arthritis and proposes common pathogenic mechanisms that may be the driving forces of the chronic viral arthritic diseases. It should be emphasized that the mechanisms may involve exceptionally autoreactive T and B cells but more commonly involves a crosstalk between persistently infected synovial fibroblasts and macrophages, contributing to chronic inflammation as described in several chronic fibrotic disorders.[26]

## KEY EXAMPLES OF ARTHRITOGENIC VIRUSES

### Parvovirus B19

Parvovirus B19 has long been known to be associated with arthritis.[27,28] B19 is the smallest single-stranded DNA virus, of 6 kb and 20 to 25 nm in diameter. The genome encodes for two structural proteins, VP1 (nucleotides 2444–4786) and VP2 (nucleotides 3125–4786), and for the major non-structural protein NS1 (nucleotides 436–2451).

Parvovirus B19 infection may be particularly deleterious during pregnancy because of the consequences on the fetus.

The critical time of infection is during the first 20 weeks of gestation, when the fetal immune system is thought to be immature and red cell mass increases more rapidly, resulting in inhibition of erythropoiesis. B19 is the cause of erythema infectiosum (also known as *fifth disease*), a common childhood rash, and of various joint complications especially in adult women, although many B19 infections remain subclinical. The seroprevalence increases with age, and more than 70% of adults are seropositive.[29] Parvovirus B19 is mainly transmitted by respiratory aerosol spread from individuals with acute infection.

Parvovirus B19 replicates in human red blood cell precursors of the bone marrow.[30] This leads to transient arrest of red cell formation. Hence, B19 infection can lead to transient aplastic crisis manifesting as severe anemia. B19 infection also affects other hematopoietic cell lineages and causes cytopenias of various types. B19 DNA or antigen has furthermore been found in the fetal heart, liver, spleen, kidney, lung, muscle, and brain, and in the heart, lung, liver, kidney, testes, cerebrospinal fluid, and synovium of children or adults. The main cellular receptor of B19 has been identified as the P antigen of the blood group P system.[31] P antigen, also known as *globoside*, is present on erythrocytes, erythroblast, megakaryocytes, endothelial cells, fetal liver, and heart skeletal muscle cells. B19 also has two coreceptors, $\alpha 5\beta 1$ integrin and KU80 nuclear autoantigen.[32]

Immunity after infection with B19 is conferred by a B cell immune response with development of neutralizing antibodies.[33] T cell–mediated responses are also involved and directed essentially against the capsid proteins VP1 and VP2.[34]

B19 is the object of intense investigations to clarify whether it is able to trigger autoimmune diseases. It has been suggested that it might be a major contributing factor or the precipitating agent of several autoimmune disorders including RA, systemic lupus erythematosus (SLE), anti-phospholipid syndrome, systemic sclerosis, and vasculitides. The joint manifestations sometimes mimic those of RA and as many as approximately 50% of patients with chronic B19 arthropathy meet the criteria of the American College of Rheumatology (ACR) for RA, suggesting that the persistence of the virus may be involved in the initiation and perpetuation of the disease.[35,36] The involved joints, mainly wrists, knees, and the small joints of the hands, are painful, swollen, and often symmetrically affected.

The onset of arthralgias coincides with the detection of circulating immunoglobulin (Ig)M and IgG antibodies against the viral structural proteins, suggesting that the deposition of immune-complexes in the synovial membranes may be responsible for the onset of the symptoms, as happens for erythema infectiosum. Parvovirus B19 DNA can be detected in synovial fluid and cells, and synovial biopsy specimens of affected joints revealed infection of $CD20^+$ B cells or $CD3^+$ T cells by double immunostaining.[37,38]

Molecular mimicry between host and viral proteins seems to be the main mechanism involved in the induction of autoimmunity. B19 infection has been associated with production of antibodies directed against a plethora of autoantigens including nuclear antigens, rheumatoid factor (RF), neutrophils, cytoplasmic antigens (CA), mitochondrial antigens (MA), smooth muscle actin (SMA), gastric parietal antigens, and phospholipids.[39] For instance, Lunardi and colleagues reported that antibodies against B19 viral proteins reacted specifically with human keratin, type II collagen, single-stranded DNA, and cardiolipin.[40] More importantly, levels of reactivity against keratin and type II collagen were correlated with clinical hallmarks, and the main autoantigen specificity in which Igs from patients with arthritis reacted preferentially with type II collagen, whereas Igs affinity purified from patients with skin rashes reacted preferentially with keratin. To confirm a role of the virus in inducing an autoimmune response, BALB/c mice were immunized with the viral proteins and autoantibodies against keratin, type II collagen, and cardiolipin, as well as single-stranded DNA, were detected in the majority of the mice that developed a strong antivirus response.

In addition to RA, parvovirus B19 infection has been associated with a variety of other autoimmune diseases, including juvenile idiopathic arthritis, SLE, progressive systemic sclerosis, Sjögren's syndrome (SS), primary biliary cirrhosis, polymyositis, and dermatomyositis.[8] In patients with systemic sclerosis, the presence of parvovirus B19 in bone marrow and/or skin biopsy specimens has been reported from a significant number of patients. Interestingly, the same authors found high levels of B19 DNA and TNF expression in endothelium and fibroblasts of scleroderma patients.[41] The degree of viral transcript expression correlated with active endothelial cell injury and perivascular inflammation, features considered to be important in the initial phases of the disease.

B19 can induce in vitro an invasive phenotype in normal human synovial fibroblasts, but mechanisms involved in cell infection and cell polarization remain largely ill characterized.[42] These experiments are now highly warranted to better establish biologic links between the capacities of viruses to polarize directly the aggressive phenotype of the resident cells of the joints.

## Rubella Virus

Rubella virus is the sole member of the genus *Rubivirus* and belongs to the Togaviridae family together with alphaviruses (see subsequent text). Rubella is an enveloped single-stranded RNA virus of 9757 nucleotides in length, which contains two long open reading frames, the 5′ proximal, which encodes nonstructural proteins, and the 3′ proximal, which encodes the structural proteins (capsid, E1, and E2). The virion is spherical and measures 50 to 70 nm in diameter, with a 30 nm dense core.[43]

Transmission is by nasopharyngeal secretions. Most cases of infection lead to a mild, self-limiting, measles-like disease, but major concern arises when rubella infects the fetus, which can lead to miscarriage or congenital rubella syndrome (CRS). In CRS, rubella virus is able to infect the placenta, spread to the fetus, and alter the function of many organs and causing systemic inflammation.[44]

Rubella E1 protein binds to myelin oligodendrocyte glycoprotein (MOG), and ectopic expression of MOG on nonpermissive cells will contribute to infection.[45] Moreover, there is a high level of homology between rubella E2 protein and MOG, which could explain the ability of antibodies against rubella to cause demyelination at least in vitro.[46]

Joint symptoms are a complication of naturally acquired rubella and have been reported to occur in more than 50% of adult females with rubella but are rare among children and adult males with rubella.[47] Symmetric or migratory arthralgias are more common than synovitis. Morning stiffness is prominent, and symptoms usually resolve during a few days to 2 weeks. Proximal interphalangeal, metacarpophalangeal, wrist, elbow, ankle, and knee joints are most frequently affected. Periarthritis, tenosynovitis, and carpal tunnel syndrome may be seen. In some patients, symptoms may persist for months to years. Following vaccination, joint symptoms occur less frequently and are usually less severe and of shorter duration than those that occur following naturally acquired rubella.[48] Live attenuated rubella vaccines have also caused a high frequency of postvaccination myalgia and paresthesia—symptoms similar to those in natural infection—beginning 2 weeks after inoculation and lasting less than a week. However, in some patients, symptoms may persist for more than a year. RA27/3, the vaccine strain in current use, may cause postvaccination joint symptoms in 15% or more of recipients.

Persistent rubella infection may be established in synovial cell cultures and, as described, in tissues.[49,50] Rubella-specific antibody titers in the synovial fluid of some patients with chronic arthritis are higher than those in serum, suggesting local synthesis of specific antibody. Persistence of rubella virus is also suggested by previous studies, which demonstrated that virus-specific IgM may persist for as long as 4 years following both natural infection and vaccination.[48] The presence of rubella RNA in synovial tissues from patients may be the result of reactivation and a result of immunodeficiency or declining immunity in old age.[51]

Rubella arthritis needs to be differentiated from other viral arthritides and from inflammatory arthritides, including RA. It may be clinically confused with parvovirus B19 infection, but serologies differentiate the two infections. NSAIDs are useful to control symptoms.

## Chikungunya Alphavirus

CHIKV[11] is an enveloped RNA positive-strand alphavirus of 12 kb belonging to the Togaviridae family, transmitted by *Aedes (Ae)* mosquitoes.[52] Aedes albopictus, the main competent vector of CHIKV, has nowadays become indigenous to many places throughout the world. The alphavirus group comprises 29 viruses, six of which can cause human joint disorders (arthralgias evolving into arthritis), namely CHIKV, O'Nyong-Nyong virus, Semliki forest virus (Africa, Asia, Europe), RRV (Australia and the Pacific), Sindbis virus (SINV; cosmopolitan), and Mayaro virus (MAYV; South America, French Guyana).

Several million CHIKV cases in humans have now been described in Africa, Southeast Asia, islands of the western and eastern Pacific and the Indian Ocean, and the Middle East (for review see[53]). Recent CHIKV outbreaks have been reported since November 2013 and have spread to several parts of Central and Latin America.[54]

CHIKV infection of humans results in a brief, usually 5 to 7 day viremia, which is in principle controlled primarily by type I IFN and antibodies.[55-57] However, CHIKV disease is often debilitating and associated with persistent arthralgias and arthritis that can last from weeks to months.[12,58] Many of the chronic patients do not respond well to usual analgesics, suggesting that the nature of chronic pain may be not only nociceptive but also neuropathic.[59] The mean pain impact on life activities calculated from the Brief Pain Inventory (BPI) was significantly higher in patients with chronic pain than in patients without it. Persistent symptoms, mainly joint and muscular pain, have been reported several months after CHIKV infection.[60,61] Long-term CHIKV rheumatic manifestations are frequent underlying postepidemic conditions. Predictors of nonrecovery include patient age older than 45 years, severe initial joint pain, and presence of underlying osteoarthritis.[61,62] Rheumatic manifestations in as many as 50% of the adult patients typically consisted of a febrile arthritis mainly affecting the extremities (ankles, wrists, phalanges).[61-67] Typically, the joint symptoms occurred in a fluctuating manner (often perceived as infectious relapses by the patients) but did not change anatomic location. Pain within or around tendons was also a common trait and evolved to tenosynovitis. Chopra et al.[68] reported high levels of CHIKV IgM antibodies in a cohort of Indian patients with post-CHIKV RA-like illnesses. These patients were clearly naïve for musculoskeletal disorders prior to CHIKV infection. Surprisingly, few were positive for RF or anti-citrullinated protein antibodies (ACPAs), and these findings were confirmed in a more recent survey of CHIKV patients with chronic arthralgias for 36 months postinfection.[61] Tenosynovitis/enthesopathy rather than synovitis was evidenced by ultrasonography in several cases, and these unique observations are in agreement with our radiograph imaging of enthesitis in post-CHIK RA patients in la Réunion.[24] Patients with a diagnosis of RA following CHIKV infection were given a classical disease-modifying anti-rheumatic drug therapy with MTX (as much as 0.3 mg/kg/week), sulfasalazine (1.5 g to 3 g/day), leflunomide (10 to 20 mg/day), or hydroxychloroquine (200 to 600 mg/day). In case of inadequate response to MTX, treatment was successful with TNF blockers (etanercept, adalimumab).[69] While the chronic disease progresses, more severe arthritis was reported 1 to 2 years post-CHIKV infection. Some patients with chronic rheumatic symptoms manifested progressive erosive arthritis.[63,67,70] In Manimunda's study, it was confirmed that the levels of RF ACPAs were not elevated in contrast to what is known in traditional RA.[67] In the same study, one-third of the patients who had joint pain met the ACR criteria to classify them with RA. The MRI findings were joint effusion, bony erosion, marrow edema, synovial thickening, tendinitis, and tenosynovitis.

CHIKV infection has been reported in multiple organs of the body and particularly the synovial tissues in humans and animal models.[55,57,71-73] In vitro studies have been instrumental for the comprehension of CHIKV tissue tropisms and to provide insights into the causal pathogenic mechanisms. The main target cells for CHIKV infection and replication are fibroblasts, as described in 1970s.[74] Recent studies support this finding, and CHIKV readily infects human fetal lung fibroblasts (MRC-5 cells) as well as human synovial and skin fibroblasts.[16,75,76] Not all fibroblasts are equally susceptible to CHIKV infection. Resting fibroblasts, as well as a subpopulation of synovial fibroblasts ($CD141^+$/$CD90^+$), manifest some resistance through mechanisms still largely unknown.[16,75] CHIKV can also infect epithelial cells

(e.g., HeLa, HEK293, but not A549), endothelial cells, hepatocytes (carcinoma HuH7), neurons, astrocytes, neuroblastoma cell lines (e.g., SH-SY5Y), and muscle satellite cells.[72,75,77,78] The nature of the receptor that mediates virus entry remains to be characterized. Evidence from biopsies of infected human patients showed that CHIKV antigens were detected mostly in cells located in the skeletal muscle epimysium, of the joint capsule, and of the dermis.[55] On the contrary, immune cells, such as monocytes, lymphocytes, dendritic cells, natural killer (NK), and their transformed cell line counterparts (e.g., THP1, U937, H9) are not permissive to infection by CHIKV.[75,77] However, human monocyte and macrophage infection remains controversial, and it is likely that they could be infected but with a poor capacity to replicate CHIKV.[73,75]

There are very few studies to support the idea that alphaviruses will contribute to chronic RA-like diseases through the production of autoantibodies against self-antigens, as described for B19, EBV, or HCV. One study from Sane and colleagues reported that Finnish patients with Pogosta disease following SINV infection had autoantibodies to NA, MA, and RF at a higher prevalence compared with healthy Finnish patients at 3 years postinfection.[79] Interestingly, the ACPAs were detected only in 1 patient out of 49, who was also positive for RF. It will remain to be determined whether this autoimmune profile is more prominent in recovered Pogosta patients versus those with long-term arthritis.

## Epstein-Barr Virus

EBV has been found in association with several common autoimmune diseases, like RA, SLE, and multiple sclerosis.[7,80] EBV belongs to the genus lymphocryptoviruses within the subfamily gammaherpesvirus of the herpesvirus family. It is the fourth member of this family. Herpesviruses are large DNA viruses with a linear double-stranded DNA genome inside a membrane-coated icosaedrical capsid. The EBV genome has a length of 172 kb. EBV has strong tissue tropism for B lymphocytes. The virus is associated with a wide variety of neoplasms, including lymphoid tumors like Burkitt's lymphoma, Hodgkin's disease, NK T cell lymphoma, and epithelial malignancies, especially undifferentiated nasopharyngeal carcinoma, gastric carcinoma, and carcinomas of the salivary glands. The virus is shed into the saliva of persistently infected individuals who spread the virus to uninfected individuals. When transmitted orally, EBV will initially infect either epithelial cells or resting tonsillar B lymphocytes. EBV binds through its viral envelope glycoprotein gp350 to the complement receptor type 2 (CR2/CD21) that is primarily expressed on B cells.[81] This receptor can also bind to IFN-α, but the role of such molecular interactions in the IFN-mediated anti-viral response is unknown.[82] B cell–bound virions can also efficiently transferred to $CD21^-$ epithelial cells, which act as helpful enhancers for transferring the virus to others cells (possibly to fibroblasts), and for establishing latency in B and other cells.[83]

Both the latent and lytic EBV proteins are potent immunogens and elicit vigorous B and T cell responses. In immunosuppressed and immunodeficient patients, or in individuals with a functional deficit of EBV-specific T cells, lytic EBV replication is regularly activated, and an increased viral load can be detected in the blood.[7] Enhanced lytic replication results in new infection events and EBV-associated transformation events, and seems to be a risk factor both for malignant transformation and the development of autoimmune diseases. It is conceivable that an increased load or altered presentation of a limited set of lytic or latent EBV proteins that cross-react with cellular self-antigens triggers and perpetuates the pathogenic processes that result in arthritis, multiple sclerosis, and SLE.

Of critical note, $EBV^+$ B cell lymphomas have been reported to develop in patients with RA when MTX is used for immunosuppression, which is not the case for other immune-modulating drugs.[84] It has been proposed that MTX could induce lytic EBV replication in latently infected $EBV^+$ cell lines in vitro. Thus MTX may promote the generation of lymphomas in RA and polymyositis patients by its immunosuppressive properties, combined with a specific reactivation of latent EBV genomes.

Although a causal role of EBV in the generation of malignancies is established, a causal role in the generation of autoimmune diseases is circumstantial. However, cross-reactivity between viral antigens and self-antigens and the immortalization of pre-existing autoreactive B cells through infection with EBV with the consequent production of autoantibodies may be plausible viral mechanisms for triggering autoimmunity. Strong genetic risk factors for RA are the alleles that contain peptide sequence homologies to EBV glycoprotein gp110 (BALF4).[85] BALF4 is normally one of the most abundant EBV proteins in late lytic infection and also serves as a target of antibody-dependent cell-mediated cytotoxicity against EBV-infected cells. The BALF4 open reading frame contains the sequence QKRAAQRAA, which is highly homologous to the RA susceptibility determinant. QKRAA is found in certain class II HLA DRβ chains, such as DR4. Carriers of this shared epitope have significantly higher RA risk through smoking compared with nonsmoking shared epitope carriers and develop autoantibodies against citrullinated self-antigens.[86]

## Hepatitis C Virus

HCV[6] is a positive-strand RNA virus of the family Flaviviridae. Studies of this virus have made huge leaps forward since the implementation of efficient cell culture systems. Worldwide, more than 130 million people are chronically infected with HCV. The viral genome consists of a single open reading frame that is less than 10 kb long. The proteins of this virus are arranged along the genome in the following order: N terminal-core-envelope (E1)–E2–p7-nonstructural protein 2 (NS2)–NS3–NS4A–NS4B–NS5A–NS5B–C terminal.

Acute infection goes along with mild and generalized symptoms, and therefore mostly remains undiagnosed. In more than half of the patients, however, the infection persists and, during the years, can cause liver damage such as fibrosis, cirrhosis, or hepatocellular carcinoma. Viral antigen is detectable within the first weeks of exposure together with a rise in serum liver transaminases. Antibodies develop and clear HCV in some patients; however, in chronic HCV infection, viral antigenemia and HCV RNA persist despite

humoral and cellular immune responses. There is also some evidence to suspect a role for HCV-associated autoimmunity for a broad spectrum of autoimmune diseases, including RA.[6] Although this association may be sporadic or indicate an increased incidence of HCV infection in patients with autoimmune disease, case reports documenting the occurrence of acute and chronic HCV infection before the development of autoimmune disease suggest a causal role in individuals who may be predisposed to the development of autoimmunity. Liver biopsy in HCV-infected patients is useful to establish disease severity and to exclude other causes of hepatitis such as alcoholism or hemochromatosis. A probable role for HCV infection in autoimmune hepatitis is emerging and with the detection of autoantibodies such as ANA and anti-SMA.

Polyarthralgias and polyarthritis have been associated with HCV infection, and HCV RNA has been isolated from synovial fluid.[87] Patients with chronic HCV associated with polyarthralgias/myalgias will have elevated levels of RF and ANA without anti-DNA antibodies.[87,88] The optimal treatment for HCV-associated polyarthritis has not been determined, but MTX has been used with some success and minimal complications.[89]

Diverse receptors or factors are involved in HCV infection and include CD81, scavenger receptor class B type I (SR-BI, also known as *SCARB1*), and claudin-1. Occludin is also an essential HCV cell entry factor.[90] We don't currently know whether synovial fibroblasts, which express many of the aforementioned receptors, can be infected by HCV and whether this could affect cell behavior.

## Arthritogenic Viruses Use the Innate Interferon-Type I Response to Favor Persistence

The role of our immune system (innate and adaptive) is to rapidly control infection by viruses, for instance, at the major portals of entry (skin, nasopharynx) and before dissemination to other organs.[91] To initiate an effective antiviral immune response, all cells should be capable of sensing and responding appropriately to pathogens. This coordinated response should in principle limit viral spreading and persistence through the mobilization of adaptive immune T and B cells.[92]

A growing number of germ-line pattern recognition receptors (PRRs) have been characterized and are expressed on immune as well as nonimmune structural cells. These receptors are capable of recognizing a plethora of conserved pathogen-associated molecular patterns (PAMPs) that do not occur under normal circumstances in the host.[93] The PRRs sense specific viral structures and induce the production of type I IFNs. Two types of PRR exist: ubiquitously expressed cytoplasmic RNA-sensing molecules and membrane-bound Toll-like receptors (TLRs). The expression of TLR is more limited than that of the cytoplasmic receptors.

The retinoic-acid-inducible gene (RIG)-I–like RNA helicase receptors (RLRs), which include RIG-I and melanoma differentiation-associated gene 5 (MDA5), are a ubiquitously expressed group of cytosolic receptors that detect viral RNA structures and induce type I IFN-α and -β production.[94] Binding of viral RNA enables interaction between the RLRs and downstream signalling molecules such as IPS-1 (IFN-β promoter stimulator-1; also known as MAVS, CARDIF, and VISA), which activate transcription factors (e.g., IFN regulatory factor [IRF]3) and regulate the production of type I IFNs. The expression of RLRs is low in the steady state but is highly induced by type I IFNs, which enhances their capacity to recognize viruses and to propagate the anti-viral response. At least ten TLRs have been identified in humans, of which three (TLR3, TRL7, and TLR9) recognize nucleic acid viral components and stimulate type I IFN production.[95] Interestingly, TLR expression is also regulated by IFNs. TLR3 is triggered by dsRNA, whereas TLR7 recognizes guanosine-rich and uridine-rich ssRNA, and TLR9 senses unmethylated cytosine–phosphate–guanine (CpG) motifs. TLR4, which is expressed on the cell surface, recognizes lipopolysaccharide from bacteria but also viral proteins and can stimulate type I IFN production.[96]

Release of type I IFN from infected cells results in autocrine and paracrine stimulation of the IFN-α/β receptor (IFNAR), which leads through associated tyrosine (TYK) and Janus kinases (JAK) to the phosphorylation of STAT (signal transducers and activators of transcription) 1 and 2. STAT1/2 heterodimers associate with IRF9 and bind to IFN-stimulated response elements (ISREs) present in the promoter region of the IFN-stimulated genes (ISGs).[97]

ISG-encoded proteins represent the anti-viral effector molecules that directly inhibit molecular and biochemical activities required for virus replication. Expectedly, type I IFNs are essential for the anti-viral activities against many arthritogenic viruses as demonstrated in vitro and in vivo.[55,75,98,99] However, many viruses (including CHIKV) have been reported to block nearly all steps of the IFN regulatory pathway. This includes the disruption of dsRNA and IFN receptor/JAK–STAT signaling events, the inhibition of IRF and nuclear factor-κB (NF-κB) functions, and other mechanisms that target the anti-viral actions of specific ISG products.[100-102]

The anti-viral molecules induced by IFN include members of the apolipoprotein B mRNA-editing enzyme catalytic polypeptide (APOBEC) family and which can mutate viral genomes, the Mx GTPase, an inhibitor of viral polymerases, and members of the tripartite motif family (including the autoantigen Ro/SS-A 52 kDa [Ro52, also known as TRIM21]), which can inhibit viral replication at multiple stages in the life cycle. Other anti-viral molecules are, for example, RNA-activated protein kinase (PKR).[103]

Immune recognition is enhanced in cells exposed to type I IFNs and controlling class I major histocompatibility complex (MHC) expression and resulting in enhanced presentation of viral but also of self-antigens for recognition by the immune system. Other changes include the induction of molecules (such as p53) that increase susceptibility to cell-death–inducing stimuli, thus enhancing the killing of virally infected cells by the immune system. Type I IFNs regulate pathways in target cells, antigen-presenting cells (such as Dc and macrophages), and effector cells (which mediate anti-viral effects as well as tissue damage).

pDCs have the unique capacity to rapidly secrete large quantities of type I IFNs upon recognition of nucleic acid structures by TLR7 or TLR9.[104] These cells are ideally suited to respond rapidly to viruses in the absence of prior IFN

exposure. pDCs are, therefore, thought to have a central role in the self-amplifying nature of autoimmune diseases through the production of large quantities of type I IFNs, which mediate numerous downstream functional effects on target cells and cells of the immune system.[105]

Surprisingly, it was found recently that some parvoviruses did not induce an IFN response in normal human fibroblasts, glia cells, or melanocytes.[106] Furthermore, the authors found that parvovirus infectivity was unaffected by IFN treatment of human normal or tumor cells. The IFN-resistant phenotype of parvoviruses may give them an advantage, including the capacity to persist in tissue sanctuaries.[106] In contrast, a great deal of information has been gathered during the recent years about the innate and adaptive immune responses to clear CHIKV. Very high levels of circulating CHIKV can be reached in acute settings, ranging from $10^5$ to $10^{12}$ virus RNA particles per mL of blood during the first days of infection.[107] CHIKV is efficiently cleared within a matter of days and the symptoms usually subside within a couple of weeks, suggesting a robust and efficient innate immune response that limits systemic viral replication. CHIKV is a single-stranded RNA virus; therefore, it may be detected by TLR7 and/or TLR8 (in mice). The helicase RIG-I and MDA-5 may also be involved in the recognition of CHIKV. Moreover, CHIKV can have a double-stranded RNA intermediate during the replication cycle, which may be detected by TLR3. Recently, White et al. showed that CHIKV infection leads to activation of the transcription factor IRF3 and subsequent transcription of IRF3-dependent anti-viral genes, including IFN-β. IRF3 activation occurred via the engagement of the adaptor molecule IFN promoter stimulator 1 (IPS-1).[108] Recently, M. Alberts's team showed that CHIKV does not stimulate directly type I IFN production in immune cells such as DC. Instead, infected nonhematopoietic cells sense viral RNA in an IPS-1-dependent manner and participate in the control of infection through their production of type I IFNs.[76] Although IPS-1 signaling pathway contributes to the immune response, they also find evidence for an MyD88-dependent PRR pathway that may be critical for preventing viral dissemination.[76] CHIKV-induced type I IFN response seems to be protective in vitro and possibly induces the expression of restriction factors such as IFN-stimulated genes (ISGs) and oligoadenylate synthetase (OAS).[109,110] OAS is active against CHIKV replication in HeLa cells, and its role in other cell types needs to be further established.[109]

In patients and in the nonhuman primate (NHP) model, the secreted IFN-α response was very transient and dropped to basal levels within 24 hours, while the peak of viremia persisted for several days.[110] These data suggest that CHIKV may be capable of controlling the IFN response. Infection and replication of alphavirus usually cause a general host translational shutoff, leading to severe cytopathic activities in mammalian cells. White et al. confirmed this paradigm, demonstrating that translation of cellular (but not viral) genes is blocked during CHIKV infection.[108] CHIKV was found to trigger inactivation of the translational molecule eukaryotic initiation factor subunit 2α (eiF2α) through a PKR-dependent pathway. Moreover, Fros et al. showed that CHIKV replication is resistant to inhibition by IFN once RNA replication has been initiated, and that CHIKV actively suppresses the anti-viral IFN response by preventing IFN-induced gene expression. Indeed, CHIKV infection efficiently blocked STAT1 phosphorylation and/or nuclear translocation in mammalian cells induced by either type I or type II IFN. Nonstructural protein 2 (NSP2) was a potent inhibitor of IFN-induced JAK-STAT signaling.[101] Hence, CHIKV, like many viruses, has evolved to evade or counteract the anti-viral responses, hence, favoring viral persistence.

An additional anti-viral molecular response is reported during CHIKV infection. Macro-autophagy, referred herein as *autophagy*, is a fundamental homeostatic process that leads to the degradation and recycling of long-lived proteins and organelles.[111,112] Autophagy is first a fundamental cell-surviving process during starvation conditions, but it does also play a role in both innate and adaptive immunity in response to pathogens.[113] We have recently explored the role of the autophagy machinery in CHIKV infection and showed that cellular autophagy was promoted within CHIKV-infected cells and, furthermore, contributed to enhance CHIKV replication.[17]

A robust protective adaptive immune response develops after CHIKV infection,[114] and this is also the case for all arthritogenic viruses listed above. IgM antibodies against CHIKV can be detected in the sera of infected patients during the acute phase of the infection, and anti-CHIKV IgG antibodies, especially neutralizing, may prevent virus reinfection.[114,115] The kinetic of appearance of the IgG, sometimes within the first days postinfection, is in favor of a rapid development of a protective adaptive immune response. At the cellular levels, a major immune response in the acute stage is characterized by a rapid mobilization of $CD4^+$ and $CD8^+$ T cells. Surprisingly, the level of TNF and IL-1β was rather weak during the acute phase and not significantly elevated when compared to control groups.[107,110] Other T helper (Th)1 cytokines were elevated in acute settings (IFN-γ and IL-12), although the response seemed to be skewed toward a Th2/Th17 response as indicated with high levels of IL-4, IL-13, and IL-17.[110] Another study demonstrated a production of IL-4, IL-10, and IFN-γ in the acute phase of CHIKV associated with a robust $CD8^+$ T lymphocyte response in the early stages of the disease, and a $CD4^+$ T lymphocyte-mediated response in the later stages.[116] Of note, a specific CHIKV IgM response persisted several months after infection[117] in patients suffering from chronic arthralgias/arthritis. This observation may be related to viral persistence.

## Arthritogenic Viruses Engage Trojan Horse Scenario to Avoid Adaptive Immunity

Many studies have searched for DNA or RNA of viruses in synovial tissue or fluid samples, mostly of arthralgic patients. Many of the arthritogenic viruses aforementioned can be found in synovial tissue or fluid. The diagnostic significance of these findings depends both on the particular microbe and on the clinical context, whereby the findings should be interpreted with caution. Furthermore, for establishing the etiology of chronic arthropathy induced by latent viral infection, the concentration and the location of the pathogen (i.e., in the synovial membrane, in synovial fluid, or in the cells of the latter), might be of importance. Even

if the pathogen is found by PCR or it can be cultured from the arthritic joint, its causal role is not easy to prove.

One of the emerging paradigms is that synovial tissue cells are infected and display an altered phenotype involved in tissue injuries.

Focusing on alphaviruses, it was found that persistent symptoms, such as joint pain (arthralgia) and arthritis (not necessarily associated with bone erosions) were reported several months after CHIKV or RRV infection.[61,118] Indeed, rheumatic manifestations affect as many as 50% of the adult patients 6 to 15 months postinfection.[119,120] There is a strong body of evidence that persistent joint damage is linked with the persistence of arthritogenic alphaviruses by mechanisms still poorly characterized.[1,121,122] This hypothesis is now thoroughly tested for CHIKV; it is plausible that CHIKV hides in immune-privileged niches and that those sanctuaries contribute directly to synovial tissue damage.[12] The study of P. Roques and colleagues showed the presence of viral antigens and RNA, 3 months postinfection, in joints, muscles, lymphoid organs, and liver.[71] Of note, they found high levels of macrophage/mononuclear cell infiltration in lymphoid organs and large amounts of CHIKV antigen and viral RNA in spleen macrophages for prolonged periods (as long as 3 months), demonstrating that macrophages act as the cellular reservoirs for CHIKV persistence.[71] The same conclusions were drawn from a study in humans. Indeed, using a longitudinal study of hospitalized patients in la Réunion, the authors showed that CHIKV (RNA and protein) was found in perivascular synovial macrophages in one chronic patient 18 months postinfection.[107] Surhbier et al. confirmed this in a mouse model of acute infection.[57] Indeed, rheumatic disease was associated with a prolific infiltrate of monocytes, macrophages, and NK cells and the production of MCP-1, TNF, and IFN-γ.

As one plausible cytopathic mechanism, the authors found that CHIKV can induce apoptosis in vitro and in synovial tissues, and that completion of the apoptotic process was important for viral propagation. Furthermore, CHIKV is able to hide in apoptotic blebs to enhance viral spreading to neighboring cells, especially macrophages that will engulf the bleb.[16] This Trojan horse scenario may take place in tissues, allowing CHIKV to escape the immune response and cause chronic pathologies, such as arthritis. These infected macrophages may recapitulate humoral and cellular inflammatory processes to drive arthritis (angiogenesis, tissue remodeling, and injuries).[107] This Trojan horse scenario is a possible immune evasion strategy reported for many viruses (B19, HBV, poxvirus, HIV, vaccinia).[123-126]

## Other Mechanisms Favoring Viral Persistence Inside Synovial Tissues

Historically, it has been thought that many viruses, including B19, are by the actions of the host immune system fully removed from the body within a few weeks or months of infection. With new sensitive detection tools, such as PCR and in situ hybridization, it is becoming obvious that eradication of a virus (if not all pathogens) from the human body is seldom complete. It is, however, critically important to study also healthy controls in order to avoid misinterpretations of disease causality.

Defective interfering (DI) particles may play a role in establishing or maintaining persistent infections. DI particles are replication-deficient deletion mutants that interfere with the growth of the homologous wild-type virus. DI particles have been observed recently also in natural infections.[97,95] It has been speculated that a potentially latent B19 infection could, under certain conditions such as stress or immunosuppression (following MTX treatment), be reactivated and cause arthralgic symptoms.[48] B19 might be carried around inside macrophages or perhaps could be attached as a full virion to the surface of follicular dendritic cells.

Another possible reason for viral persistence is that the synovial tissue cells constitute a good hiding place from the host's immune defense. The dominant local cell populations in joints are synovial and cartilage cells. Synovial cells can be divided into fibroblast-like and macrophage-like synoviocytes. These cells present several distinct phenotypical characteristics compared with classic fibroblasts and tissue macrophages.[18] It may be that these cells have major immunoregulatory mechanisms to control tissue injuries but these may also be mobilized during viral infection to favor viral persistence.[127] A positive correlation was detected between $CD4^+CD25^+$ T regulatory (Treg) cell frequency and HCV chronic infection as detected by high levels of RNA titers in the liver of patients.[128] It has been proposed that Tregs may play a role in viral persistence by suppressing HCV-specific T cell responses in a cell-cell contact manner. Chronic HCV infection may also be favored, given the concomitant presence of virus-specific $CCR7^-$ $CD8^+$ T cells.[129] These $CD8^+$ Tregs are antigen specific because they can be stimulated by HCV epitopes and suppress T cell responses through the production of considerable amounts of IL-10. It remains to be addressed whether these Tregs are mobilized by other arthritogenic viruses.

## Mechanisms Involved in Chronic Arthralgias

As a testament to the major involvement of excruciating joint pains in many alphaviral arthritides in humans, the native African name for CHIKV means "that which bends up." These arthralgias can be observed through the acute phase of the infection and which will last over months and years in chronic patients.[61] Joint pains are also clinical hallmarks associated with chronic B19 or HCV infections.[130-132]

The joint is a densely innervated organ, and its sensory innervation is geared predominantly toward nociception, indicating how vital positioning sense and awareness of potentially injurious movement are to proper joint function.[133] Chronic pain pathways are subject to complex levels of control and modulation, both in the periphery and in the central nervous system. In humans, articular branches of the tibial nerve that innervate the posterior knee joint capsule contain 70% to 80% unmyelinated C fibers and sympathetic nerves and which have also been associated with pain.[134] Nociceptors (nerve endings involved in pain) are abundant in the joint capsule, ligaments, periosteum, menisci, subchondral bone, and synovium. Because cartilage is abneural, it is not involved in nociception of the joint.

Nociceptors express a broad range of receptors for ligands that will induce action potentials when the receptors are engaged and transmitting nociception to the brain.[135] These

ligands include cytokines, chemokines, neuropeptides, and prostaglandins (PG), which can all form part of the biochemical milieu in the joint persistently infected by arthritogenic viruses.[12] As a result of this peripheral sensitization, joint movement within the normal range becomes painful.

TNF, IL-17, and IL-6 are inflammatory cytokines abundantly expressed in response to infection by many of the arthritogenic viruses.[5,12] High concentrations of pro-inflammatory factors such as IFN-α, IL-6, and IP-10 were also found at higher levels in serum of patients with CHIKV-induced polyarthritis than in noninfected healthy individuals, indicating their potential causative role in chronic joint and muscle pains.[116,136,137] These molecules can cause prolonged mechanical hypersensitivity and sensitizing joint nociceptors to mechanical stimuli.[135] The pro-inflammatory cytokines IL-1β and TNF can directly affect sensory neurons and can also trigger pain via downstream mediators such as other cytokines, chemokines, PG, neurotrophins, nitric oxide (NO), kinins, lipids, adenosine triphosphate (ATP), and complement anaphylatoxins.[133] Interestingly, it has been reported that IFN produced by CHIKV-infected fibroblasts induced elevated expression of PG.[138] HCV, and particularly the NS3 viral protein, is also known to modulate cyclooxygenase 2 activity and hence PG synthesis.[139,140] All in all, PG may contribute to mechanisms of nociceptor activation and sensitization. In addition, the activation of complement system and the production of complement anaphylatoxins in RRV-infected joints may contribute to arthralgia.[141]

Inflammatory cytokines can also enhance local levels of nerve growth factor (NGF), a major contributor to peripheral hypersensitivity.[142] The binding of NGF to its high-affinity receptor, TrkA, on peripheral nociceptors causes rapid potentiation of the thermosensitive ion channel TRPV1 (transient receptor potential cation channel, subfamily V, member 1) and lowering pain threshold and contributing to pain hypersensitivity. The authors currently do not know whether arthritogenic viruses may affect the biology of NGF in the joint, but it has already been reported that alphaviruses such as SINV can increase NGF production by glial cells.[143]

Nociceptors have been reported to express TLRs, which recognize a variety of alarmins released during tissue injury and contribute to pain generation. The primary function of these alarmins is to boost innate and adaptive immune cell anti-viral activities, but could also contribute to chronic inflammation and joint pain.[21,22]

## Mechanisms Involved in Chronic Inflammatory Viral Arthritis Resembling Rheumatoid Arthritis

RA is an extremely widespread systemic autoimmune heterogeneous disorder that is characterized by an antigen-driven immune response against self-antigens with the destruction of host tissue with a highly disabling impact that affects approximately 1% of the world population.[13] A hallmark of RA is its self-sustaining and autoamplifying nature, in which immune-mediated tissue damage and tissue repair collaborate in a feed-forward loop to provide the destructive power and the fuel that sustain the inflammatory process.

CD4 and CD8 T cells, NK cells, and macrophages contribute to the local and chronic inflammation of the joints. Secretion of inflammatory cytokines such as IL-1β, IL-6, and TNF[13] play a pathogenic role in the disease process. Overproduction of pro-inflammatory cytokines is believed to be orchestrated predominantly by macrophage-like synoviocytes.

Fibroblast-like synoviocytes invade the cartilage and contribute to joint destruction. The activation and differentiation of resident macrophages into osteoclasts is a key process leading to bone erosion.

Women are three times more affected than men, which has been interpreted as the influence of the pro-inflammatory estrogens, but also additional hormonal influences (e.g., prolactin) and additional environmental factors (e.g., socioeconomic status and lifestyle). Cigarette smoking is the strongest environmental risk factor for RA, increasing the risk 3- to 13-fold, depending on the number of pack years.

The mode of pathogenesis in virally induced arthritis might be mediated through different routes, but the outcomes are remarkably similar, with chronic inflammation driven in the various syndromes including RA. Several studies have already suggested that macrophage recruitment and subsequent secretion of pro-inflammatory cytokines and chemokines play a major role in the development of arthritis in alphavirus infection.[71,107,144,145] Other cellular injuries could be direct cellular lysis of virally infected cells, indirect effects mediated by the immune response and/or enhancement of the invasiveness of synovial fibroblasts (acute or chronic arthritis), and production of immune complexes.[12]

More recently, it has been demonstrated that osteoblasts as well as synovial fibroblasts infected by CHIKV could drive osteoclastogenesis in vitro, and which, in essence, may contribute to joint damage.[146,147] Osteoclasts are specialized cells derived from the monocyte/macrophage hematopoietic lineage that develop and adhere to bone matrix, then secrete acid and lytic enzymes that degrade it in a specialized, extracellular compartment.[148] Osteoprotegerin (OPG), receptor activator of NF-κB (RANK) and RANK ligand (RANKL) together regulate osteoclast function. CHIKV and RRV patients demonstrated high levels of RANKL and low levels of OPG, which would favor the appearance of macrophage-derived osteoclasts in the joints.[5,149]

Chen et al. reported recently using a CHIKV infection mouse model that blood monocytes were recruited to sites of infection through the action of chemokines such as CCL-2 and differentiated into osteoclast-like cells, leading to bone erosion. Furthermore, they observed that treatment with an IL-6 neutralizing antibody reduced bone loss and RANKL/OPG ratios in sera of mice.[5] Bindarit, an inhibitor of CCL2 action, was also able to control for the osteoclastogenic activity of CHIKV.[149]

## Treatment and Prevention

Arthralgias and arthritis postviral infection are mainly treated with analgesics, NSAIDS, which provide some symptomatic relief but do not significantly modify the underlying disease process. Chronic arthritis lasting more than 3 months and treated with MTX showed good response,

probably according to its anti-proliferative action on invasive fibroblast or for its capacity to control the pro-inflammatory activities of alarmins such as HMGB1.[150,151] Whether chloroquine may be useful as a prophylactic treatment or in the case of chronic infection needs further investigations.[152] Several molecules are in development and have been tested in animal models. IFN-α treatment was able to prevent arthritis in mice but only if given before infection, suggesting that IFN-α could not be a potential therapy.[57] A high level of CCL2 is produced following alphaviral infection in humans,[107,110] as well as in mice suffering from polyarthralgia and polyarthritis postalphavirus infection.[57,153] By reduction of the inflammatory infiltrate in infected mice, bindarit, an inhibitor of CCL2, brings relief to disease symptoms related to tissue damage by reducing the influx of inflammatory cells.[153]

Vaccination remains the best strategy to prevent most vector-borne diseases. Ideally, vaccines should combine low cost, single-dose efficacy and rapid and long-lived immunity with negligible risk of serious adverse reactions. For example, recombinant CHIKV vaccines are under development in mouse or macaque models, using different new technologies.[154-156]

## CONCLUSION

Our understanding of the pathologic mechanisms involved in chronic arthralgias and arthritis postviral infection is still in its infancy, given that several intricate humoral and cellular pathways are involved. Causal links will need to be verified in animal models, which can be controlled for immune status, immune senescence, or any other comorbidities, such as chronic systemic inflammation (e.g., type II diabetes). The development of animal models of chronic and flaring viral arthritis will be instrumental for screening new drug treatments and vaccines and to evaluate the short- and long-term effects of immunomodulation therapies of these arthritides.[3] This is critical and will need intensive investigations to improve animal models currently reported in the literature that do not seem to develop chronic joint inflammation. Gene and protein profiling studies will be required to address the phenotypic polarization of the synovial cells (fibroblasts and macrophages) that are chronically infected and which will contribute to aggressive destruction of the joints. It may be possible that viruses may control many of the inflammatory pathways, which may be of further interest to understand RA and identify novel therapeutic avenues.

CHAPTER 115

# Rheumatic Fever and Post-streptococcal Arthritis

Luiza Guilherme • Pedro Azevedo Ming • Jorge Kalil

**KEY POINTS**

- Rheumatic heart disease, the most common cause of acquired valvular disease in the world, is responsible for approximately one in four episodes of heart failure in endemic countries.
- Acute rheumatic fever (ARF) follows nontreated group A streptococcus throat infection, is mediated by immune mechanisms, and is controlled by genetic makeup.
- ARF rarely occurs before age 3 years and occurs infrequently after age 15 years. The majority of cases occur between ages 4 and 9 years.
- According to the World Health Organization ARF criteria, migratory polyarthritis, carditis, erythema marginatum, Sydenham's chorea, and subcutaneus nodules are major manifestations and arthralgia, fever, first-degree heart block, and elevated inflammatory markers are minor manifestations.
- Symptoms begin approximately 2 to 3 weeks after group A streptococcus infection, with the exception of chorea, which normally begins after the fourth to sixth week.
- Inflammation tends to be more intense in small children, who often exhibit greater prostration, fever, and carditis, whereas adults tend to exhibit a greater incidence of arthritis.
- Autoimmune reactions are mediated by both humoral and cellular immune response.

Rheumatic fever (RF) and rheumatic heart disease (RHD) occur in young, susceptible people who have not received treatment for group A streptococcal (GAS) infection. In this chapter, we briefly describe the etiologic agent and review several genes involved in the development of inflammatory and autoimmune lesions. Of note, the role of class II human leukocyte antigen (HLA) alleles is described in association with the disease and its function in antigen presentation to T cell receptors, which activates the adaptive branch of the immune response. The mechanisms that underlie organ-specific lesions are also discussed. Both cellular and humoral immune responses are involved in the autoimmune reactions, and T helper (Th)1 and Th17 inflammatory cytokines are mediators of rheumatic heart lesions. Clinical spectra and treatment are presented, along with perspectives regarding a vaccine for *Streptococcus pyogenes*.

## RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

### Etiologic Agent *(S. pyogenes)*

RF is always preceded by infection with group A streptococcus. The streptococci were classified by Rebecca Lancefield in 1941, who identified carbohydrates on the cell walls of the bacteria and classified them as groups A, B, C, F, and G based on the types of cell wall polysaccharide.

Group A is characterized by the presence of N-acetyl-β-D-glucosamine and rhamnose in the cell wall and is responsible for the development of RF and RHD. These bacteria contain M, T, and R surface proteins and lipoteichoic acid, which are involved in bacterial adherence to epithelial cells of the throat.

M protein, the major antigen, is composed of approximately 450 amino acid residues that extend from the cell wall. The N-terminal portion of this protein is highly variable and defines the emm type that is responsible for the antigenic diversity of the bacteria. According to the Centers for Disease Control and Prevention, more than 200 emm genotypes currently exist worldwide, with a variable distribution depending on the region.

The diversity of *S. pyogenes* is also influenced by social and economic conditions. It is accentuated in low-income countries, likely because of the lack of treatment, resulting in the spread of bacteria and favoring genetic mutations. Similarities in the distribution of emm-type strains have been observed in high-income countries, Asia, the Middle East, and Latin America, in contrast to those found in Africa and the Pacific region.[1] It is interesting to note that most of the streptococcal strains identified and described in this study were associated with the development of RF and RHD. The most frequent strain in most countries was emm1, which accounted for approximately 20% of the strains compared with approximately 5% in Africa and the Pacific region.[1] Interestingly, the emm1 strain is also frequently associated with post-streptococcal glomerulonephritis and invasive disease.[2,3]

Recently, an analysis of 220 variants of the M protein revealed 48 emm clusters that contained closely related M proteins sharing binding and structural properties.[4] This classification could provide important information for new drug and vaccine designs for the treatment and prevention of diseases related to streptococcal infection.

The end of the C-terminal half, in contrast to the N-terminal portion, contains multiple repeat regions and

presents a high degree of conservation of approximately 70%. In addition, it is a target of vaccine development models.

## Epidemiology

The development of RF and RHD after *S. pyogenes* infection in the throat depends on the genetic background of the individual and is influenced mainly by low socioeconomic conditions that facilitate the agglomeration of people and the spread of bacteria. In poor regions of several low-income countries in which medical treatment is not available or is limited, as well as in developing nations, the burden of RF and RHD remains a challenge.[5] The risk of RF after untreated GAS pharyngitis in susceptible people ranges from 0.3% to 3%.[6]

Although recent epidemiologic information is not available, data from the past 5 to 10 years have shown that the incidence of acute RF (ARF) in some developing countries exceeds 50 per 100,000 children. The worldwide incidence of RHD is at least 15.6 million cases and is the major cause of approximately 233,000 deaths per year. The incidence of ARF varies from 0.7 to 508 per 100,000 children per year in different populations from several countries.[6] In Brazil, according to the World Health Organization (WHO) 2008 epidemiologic model and data from the Brazilian Institute of Geography and Statistics (IBGE), there are approximately 10 million cases of streptococcal pharyngitis infections. These cases could lead to 30,000 new cases of RF, among which approximately 15,000 could become cardiac lesions. One important aspect of the recurrence of RF episodes is the possibility of worsening valve damage.

## Clinical Manifestations

### Acute Rheumatic Fever

Manifestations of ARF include a constellation of symptoms that may occur in isolation or in any combination. The incidence of ARF manifestations varies in frequency and intensity among different age groups, individuals, and localities, as previously reported.[7]

ARF is rare before age 3 years and infrequent after age 15 years, with the majority of cases occurring between ages 4 and 9 years. Inflammation tends to be more intense in small children, who often exhibit greater prostration, fever, and carditis, whereas adults tend to exhibit a greater incidence of arthritis. Symptoms begin approximately 2 to 3 weeks after GAS infection (average, 18.6 days), with the exception of chorea, which normally begins after the fourth to sixth week. However, some patients appear to have a very short latent period as a result of clinically unapparent infection some weeks prior to the observed respiratory illness.

### Pharyngitis

Approximately half of streptococcus pharyngeal infections can be asymptomatic.[8] The proportion of patients in whom ARF will develop after a pharyngeal infection largely depends on characteristics of the bacteria, population, and individual. Data obtained from RF outbreaks in U.S. military camps from 1949 to 1950 suggested that ARF would develop in 2.5% of patients infected with a rheumatogenic streptococcus strain. In a similar situation in 1987, the rate of ARF per case of streptococcal pharyngitis was 1.6%.

### Arthritis

Arthritis is the most common and often the earliest major symptom of ARF, although rarely it may be preceded by carditis. The relative proportion of patients with ARF who have polyarthritis and the severity of this manifestation increase with age.[9] In the old series (1962), arthritis was present in nearly 100% of young adults, 82% of teenagers, and 66% of children.[10] Tenderness is often disproportionate to the physical findings. A significant proportion of patients exhibit an additive rather than the classic migratory pattern of involvement, which occurs mainly in adults. A monoarticular presentation occurred in only 17% to 25% of the cases in the old series,[10] but it is currently much more common, which has been attributed to the widespread use of anti-inflammatory treatments. Untreated patients typically have 6 to 16 affected joints. Knees (76%), ankles (50%), and elbows and wrists (12% to 15%) are the most frequently involved sites. The shoulder (7% to 8%) and phalangeal (7% to 8%), lumbosacral (2%), cervical (1%), sternoclavicular (0.5%), and temporomandibular (0.5%) joints are less frequently affected.[10] Articular symptoms should last a few days for each joint and not much longer than a week for each ARF attack.[6] They typically respond well to NSAIDs. Other diagnoses should be considered if this pattern is not followed.

Although arthritis is never radiographically destructive in people with RF, Jaccoud's arthropathy (chronic postrheumatic fever arthropathy) has been described in recurrent cases in the past.

### Acute Carditis

Carditis occurs in 15% to 91% of the first ARF episodes, depending on the patient selection and whether echocardiography is used for diagnosis.[10-12] Carditis affects children more often and more severely than adults, but the latter are not spared. Inflammation may involve the pericardium, myocardium, and endocardium (pancarditis), and it may be mild and silent (subclinical) or severe and lead to acute congestive failure and death. In the acute phase, endocarditis is associated with edema of the valves and possibly vegetations (marantic vegetations) that do not produce an embolism. The mitral valve is affected in almost all cases, which is attributed to the predominant migration of inflammatory cells through the papillary muscles. The tricuspid valve is also frequently affected, but rarely in a significant manner. The aortic valve is involved in approximately 20% to 30% of cases.[13] Valve involvement may lead to a new or changing murmur that is used clinically to define carditis. Mitral regurgitation is the most common acute valvular lesion and may be isolated or concomitant with aortic regurgitation. Isolated aortic regurgitation is infrequent. Typical acute-phase murmurs consist of the high-pitched, blowing, holosystolic, apical murmur of mitral regurgitation; the low-pitched, apical, mid diastolic, flow murmur (Carey-Coombs murmur); and a high-pitched, decrescendo, diastolic murmur of aortic regurgitation heard in the aortic

area. Mitral regurgitation can be caused by valvular inflammation and deformity and/or valve prolapse. The latter is caused by annular dilation and chordal elongation, and it typically involves the anterior leaflet with minimal leaflet redundancy. Rupture of the chordae tendineae is possible and often leads to acute heart failure (HF) and the need for emergency surgery. Aortic or mitral stenosis at presentation is atypical and may be a sign of previous undiagnosed RF attacks.

Congestive HF (CHF) is the most life-threatening feature of ARF and is a result of valvular damage along with heart muscle dysfunction due to myocarditis and chamber dilatation. It affects 5% to 10% of people experiencing their first ARF episode and is more frequent during recurrences. Myocarditis in the absence of valvulitis should not be considered rheumatogenic in origin. Variable degrees of heart blockage may be present, and a transient pacemaker may be required if CHF occurs.

Pericarditis is present in approximately 10% of patients and manifests clinically as pleuritic chest discomfort or pain and pericardial friction rub. Although effusion may be prominent, cardiac tamponade is rare.

### Transition from Acute to Chronic Heart Disease

Inflammatory markers normally subside within 3 months after the acute phase, but they may remain high for a much longer period in a subset of patients. The causes or prognostic implications of persistent inflammation are not known. According to the classic view, if the patient received appropriate prophylaxis and did not experience further GAS infections, then any deterioration observed after the acute attack would be a result of mechanical dysfunctions caused by the valve insufficiency (acute injury and scarification) or the slow progression of valve stenosis. It is now increasingly recognized that some local inflammation may persist in the myocardium and (mainly) the valves of some patients and that it may, to some extent, be responsible for the observed deterioration. Samples from the valve and papillary muscles of patients with chronic RHD that are collected during valve replacement procedures often show variable degrees of mononuclear or lymphocytic infiltrates and sometimes Aschoff nodules, even in patients considered to be in remission clinically and on the basis of laboratory results.[14,15] Figure 115-1 illustrates rheumatic valve lesions and infiltrating T lymphocytes. In most cases the fibrotic and neovascularization effects that are involved in healing processes do not affect the function of the valves. Nevertheless, scarring may progress over the years and affect cusps, chordae tendineae, subendocardial tissue, and the annulus fibrosus, leading to valvular thickening, stiffening, incompetence, or stenosis. The speed of scarification and progression of mitral stenosis vary between geographic areas. In countries with a low RF incidence, 20 to 40 years will pass until surgery is required, whereas in countries with a high incidence of RF, mitral stenosis is possible in patients younger than 5 years. Again, factors relating to this behavior are unknown but are believed to be linked to the degree of acute damage, recurrences, and the persistence of inflammation.

In the classic 1951 series by Bland and Duckett Jones,[11] clinical signs of rheumatic valvular disease disappeared in 17% of the patients after 20 years. However, murmurs later developed in another 44% of the patients who initially did not have clinical carditis. In total, 70% of the patients eventually evolved to chronic RHD.[11] More recently, 258 Brazilian children with ARF were followed up prospectively, and 72% and 37% of them eventually experienced chronic valvular disease based on echocardiography and clinical assessment, respectively. Severe aortic and/or mitral disease occurred in 16% of the patients. Risk factors for progression to severe chronic valvular diseases were moderate or severe acute carditis, recurrences of ARF, and a low educational level of the mother.[16]

### Indolent Carditis

Indolent carditis may be defined as carditis of insidious onset and slow progression (low acute-phase aggressiveness and absence of significant acute progression), especially in people presenting for a medical diagnosis months after the onset of RF.[17] Recognition is usually delayed, and prophylaxis is not introduced; therefore, multiple recurrences are likely to drive progression. Diagnosis is typically made by routine consultations or when symptoms of RHD are present. It is not a rare situation, especially in the developing world, but the exact incidence has not been ascertained.

### Subclinical Carditis

Subclinical carditis is defined as pathologic valvular regurgitation detected by echocardiography that is not clinically evident.[18] Its clinical importance is discussed in the Echocardiography section.

### Rheumatic Heart Disease

RHD, the most common cause of acquired valvular disease in the world, is responsible for approximately one in four cases of HF in endemic countries.[19] Chronic RHD is normally oligosymptomatic until HF is established. HF features include a third heart sound, tachycardia, dyspnea, rales, and edema. If the diagnosis is not established during the acute phase, RF often remains undetected for many people until the first symptoms of HF occur. In South Africa, 82.5% of affected children were previously undiagnosed.[20] Sixty percent of the patients who are oligosymptomatic at the time of diagnosis will not experience any progression of symptoms in 10 years. Survival is greater than 80% in such cases. After the development of New York Heart Association functional class III or IV disease, survival is estimated to be 0 to 15% over 10 years if surgery is not performed. In the presence of severe pulmonary hypertension, survival is expected to be no longer than 3 years without surgery.[21] Typically, young patients exhibit pure mitral regurgitation, middle-aged adults have mitral stenosis, and older patients present with mixed mitral valve disease.[13] RHD normally remains asymptomatic for a long period and frequently is not noticed if ARF does not manifest.

### Sydenham's Chorea

Sydenham's chorea, also known as St. Vitus dance and chorea minor, is a neurologic disorder characterized by

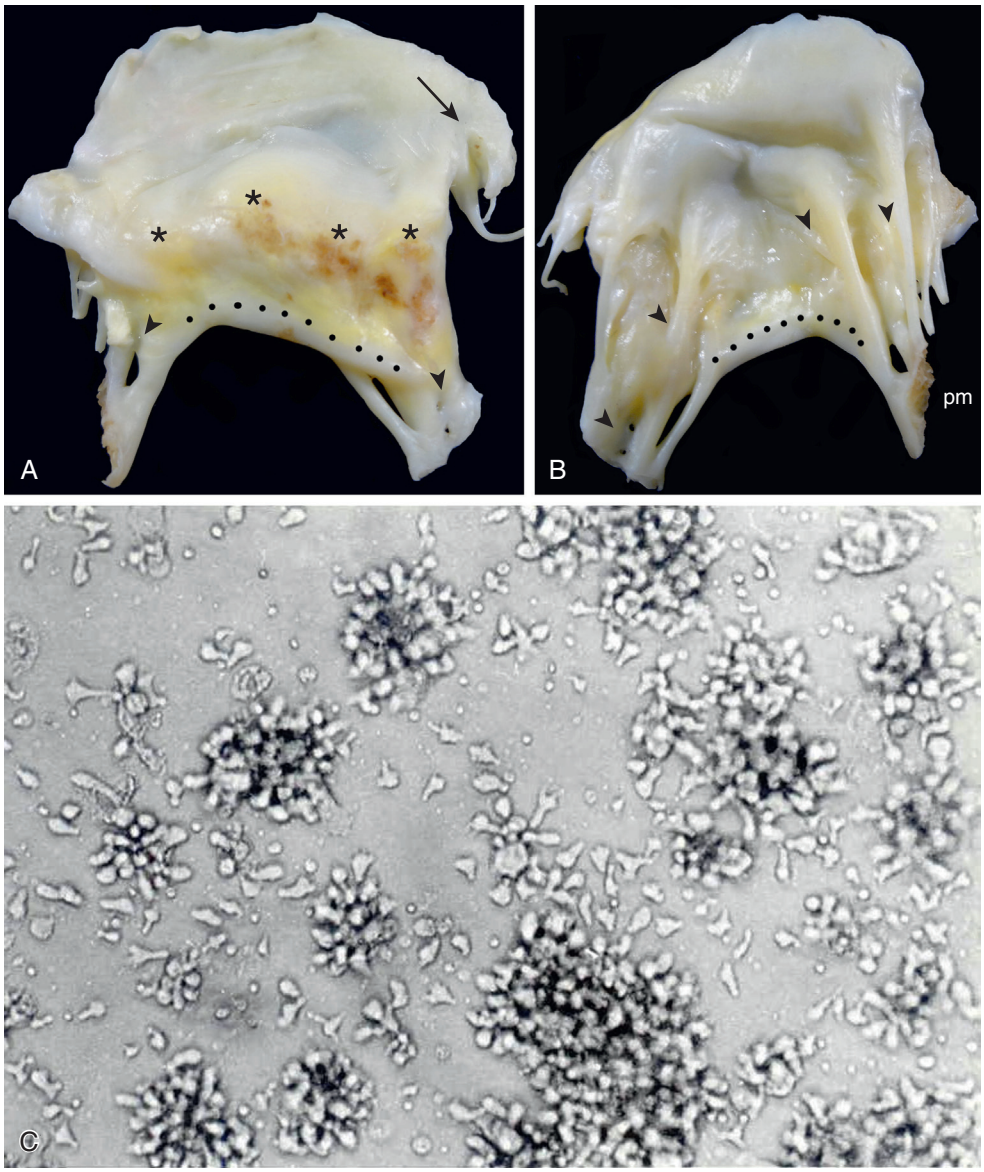

**Figure 115-1** Photograph of a mitral valve surgical specimen of a patient with rheumatic heart disease who underwent surgery for valve correction. Post-rheumatic mitral insufficiency and stenosis are shown as follows: (**A**) atrial and (**B**) ventricular aspects of the anterior mitral cusp show a thickened, calcified, and distorted leaflet with commissural adherence *(arrow)*, crescentic notching of the free edge *(dotted line)*, and calcification at the closure line (*). There is thickening, fusion, and retraction of the chords *(arrowheads)* and fibrosis in the papillary muscle (pm) tips. **C**, T cells (mainly $CD4^+$ cells) obtained by cell culture of valve fragments. Leukocytes infiltrate the myocardium and the left atrium. Later these cells go to the mitral valve, the most frequent site of valve damage, probably through papillary muscle; then they can reach the aortic valve and less frequently the tricuspid valve. A great number of infiltrating autoreactive T cells[65] that lead to the rheumatic lesions are present in the papillary muscle and valves. The inflammatory process is permanent as a result of a milieu composed mainly of inflammatory cytokines (TNF and IFN-γ) and low numbers of regulatory cytokines (IL-4 and IL-10).[77] *(**A** and **B**, Courtesy Dr. Demarchi, LMMF, Laboratory of Pathology, Heart Institute [InCor], School of Medicine, University of São Paulo, São Paulo, Brazil. **C**, Magnification 200×. Courtesy L. Guilherme, Laboratory of Immunology, Heart Institute [InCor], School of Medicine, University of São Paulo, São Paulo, Brazil.)*

emotional lability, personality changes, muscular weakness, reduced fine-motor skills, and uncoordinated abrupt, nonrhythmic, purposeless, jerky movements. Gait difficulties, headache, impaired cognition, dysarthric speech, and hypotonia are also possible features. Motor symptoms disappear during sleep; may affect the hands, arms, shoulders, feet, legs, face, and trunk; and are frequently more marked on one side. Other classic signs of chorea include tongue fasciculation ("bag of worms") and a relapsing involuntary hand grip ("milk maid's sign"). Although movements may be partially repressed by will, they can impair important daily activities. Emotional changes may precede motor symptoms and manifest through outbursts of inappropriate behavior, including crying and restlessness. In rare cases, psychological manifestations are severe and may result in transient psychosis.

In contrast to the other manifestations of RF, chorea generally occurs 6 to 8 weeks after the streptococcal infection is sustained; however, a latent period of up to 8 months has been described.[22] In the 1951 series of 1000 patients reported by Bland and Jones,[11] 51.8% had chorea. More recently, it has been reported to occur in 20% to 30% of

patients with ARF.[22] Females are affected more often than are males, and a first episode of chorea in adulthood is rare, although recurrences are more common during this period of life.

Chorea may occur in isolation or along with other RF manifestations. A recent series showed that 71% and 42% of 69 patients with chorea also had carditis based on an echocardiogram and on a clinical basis, respectively.[23] In the series by Bland and Jones,[11] chorea was associated with less severe carditis, and this manifestation is believed to have a better overall prognosis. Most patients with chorea recover spontaneously within 2 to 6 months. However, cases have been reported in which the condition persisted up to 3 years.

### PANDAS

In pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), antibodies from the sera of patients with chorea are able to bind to neuronal cells and induce the release of dopamine.[24] A subset of these patients will experience behavioral disturbances such as tics and obsessive-compulsive disorder (OCD) years after the initial manifestation of chorea. Symptoms may abruptly worsen after a new streptococcus infection. These data led to the hypothesis that this spectrum of mental disorders is a result of previous streptococcal infection in children. A strong association between OCD and the D8/17 antigen present on B cells has been described.[25] This antigen is believed to differentiate the clinical spectrum of patients who have RF with high specificity.[26] The PANDAS hypothesis remains controversial, although it is largely accepted that streptococcal infection can worsen symptoms of OCD in some patients.

### Fever

Fever may be absent, subtle, or high. Similar to subcutaneous nodules, erythema marginatum, and chorea, fever is extremely rare in adult-onset ARF. Malaise and myalgia are commonly associated with fever and may also be intense.

### Erythema Marginatum

Erythema marginatum is an evanescent, pink, nonpruritic, nontender rash that involves the trunk and sometimes the limbs but not the face. It is strongly associated with carditis. The lesion is also known as "erythema annulare" because its margins often assume the form of a ring. The border is irregular, serpiginous, and sharp on the outside but diffuse on the inside edge; it extends centrifugally while the center progressively clears. Lesions may appear, disappear, and reappear in a matter of hours and may be difficult to visualize on dark skin. A hot bath or shower may make them more evident. Erythema marginatum usually occurs early in the course of ARF, but it may occur at any time, occasionally in the chronic heart disease phase.

### Subcutaneous Nodules

Subcutaneous nodules in RF resemble those of rheumatoid arthritis in terms of having a predilection for bony surfaces or areas near tendons (elbows, knees, ankles, Achilles tendon, and occiput); however, they are smaller and more fleeting (they rarely persist for more than a month and normally subside within 1 or 2 weeks). Lesions range from a few millimeters to 2 cm in size and are firm, painless, and loose in relation to adjacent surfaces. The skin over the lesions is not inflamed. The number may vary from one to a few dozen (with an average of four). When they are abundant, the lesions tend to occur in crops and to have a symmetric distribution. Subcutaneous nodules are virtually always associated with significant chronic active carditis and are uncommon in early stages of the disease. They were described in 8.8% of the patients in the series by Bland and Jones[11] but only in 1.5% in a more recent series of 786 patients,[27] representing the least common RF manifestation.

## Genetic Associations

In autoimmune diseases, the activation of both innate and adaptive immune responses leads to tissue damage, probably as a result of a previous infection caused mainly by viruses or bacteria. In general, the control of pathogens and triggering of autoimmune reactions involve several genes.

The predisposition to develop both RF and RHD disease is associated with some class II HLA alleles, as well as single nucleotide polymorphisms in several genes related to activation of the immune response, initially against *S. pyogenes* and later against self-antigens.

The innate immune system detects pathogen-mediated injury, as well as other types of body injury, and represents the first line of immune defense. Both immune and somatic cells present receptors that are able to recognize microbial molecules called pathogen-associated molecular patterns and tissue injury-induced molecules as a sign of damage-associated molecular patterns.[28]

Most studies involve RF/RHD cohorts from diverse ethnicities and are representative of the genes involved in the development of the disease, as summarized in Figure 115-2. The genes associated with a predisposition to the disease are described, taking into consideration their role in both innate and adaptive immune responses.

### Innate Immunity

Toll-like receptors (TLRs) initiate host defense responses in multicellular organisms because they are sensors of foreign microbial products. A polymorphism of TLR-2 at codon 753 generally leads to the replacement of arginine with glutamine. The genotype 753Arg/Gln was more frequent in a Turkish ARF cohort when compared to controls and probably interferes with the recognition of *S. pyogenes* and the innate immune response against the pathogen.[29]

Mannan-binding lectin (MBL) is an acute phase inflammatory protein that binds to a wide variety of sugars on the surface of pathogens to promote phagocytosis and complement cascade activation via the lectin pathway.[30] Different variants of the promoter and exon 1 regions of the *MBL2* gene, which encodes mannan-binding lectin, have been reported in patients with RF/RHD. These studies have shown that the A allele, which encodes a high level of MBL production, is associated with the development of mitral

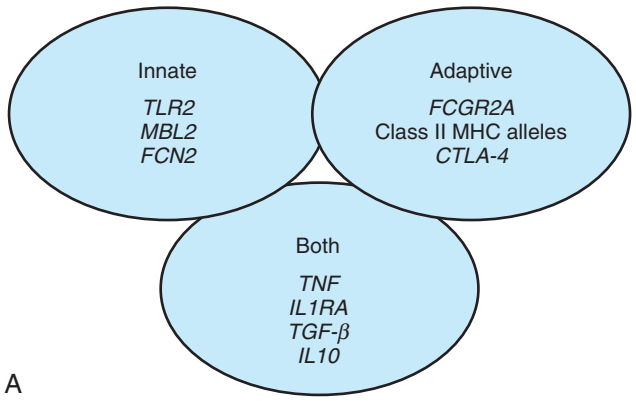

**Figure 115-2** Rheumatic fever (RF)/rheumatic heart disease (RHD) cohorts from diverse ethnicities are representative of the genes involved in the development of the disease. stenosis,[31] whereas the O allele encoding a low level of production is related to aortic regurgitation.[32] Ficolins are proteins that bind to collectin cellular receptors and also initiate the complement lectin pathway. Three ficolin genes have been identified in humans with different functions, sequences, and specificities. Polymorphisms at –986, –602, and –4 within the promoter region of ficolin 2 (*FCN2*) encoding the ficolin-2 (L-ficolin) protein are associated with the serum levels of this protein. In Brazilian patients with chronic RHD, the haplotype G/G/A (–986/–602/–4) was shown to occur more frequently than in control subjects and was correlated with low levels of this protein and consequently a prolonged infection duration or repeated streptococcal infections.[33]

## Adaptive Immunity

The *FCGR2A* gene controls the adaptive immune response and plays a role in the clearance of immune complexes by macrophages, neutrophils, and platelets. In patients with ARF, a polymorphism that typically encodes arginine (codon 131) instead yields histidine and encodes a protein with a low binding capacity to the immune complex, favoring the inflammatory response.[34]

Susceptibility to the development of RF and Sydenham's chorea or RHD was first associated with diverse class II HLA alleles (DR and/or DQ) encoded by the *DRB1* gene of the major histocompatibility complex, which is located in the short arm of human chromosome six. Several HLA-DR and/or DQ alleles have been described as being associated with the development of the disease worldwide (Table 115-1).

Briefly, HLA-DR1 was found in patients with RF and RHD from South Africa[35] and Martinique[36] and in patients with Sydenham's chorea from Brazil.[37] HLA-DR2 was detected in the black population in the United States[38] and in Mexico,[39] and DR3 and DR5 have been described in northern Indian and Turkish patients with RF/RHD.[40-42] HLA-DR4 has been found in Caucasian patients with RHD in the United States[38,42] and in patients in Saudi Arabia,[43] whereas HLA-DR6 has been detected in South Africa,[35] and HLA-DR7 has been detected in the Brazilian Caucasian and Mulatto populations,[44,45] in Egyptians[46] and Latvians,[47] and in patients from some regions of Turkey.[41,48] DR9 has been found in Caucasian Americans.[42] These data are summarized in Table 115-1.

In Egyptian and Latvian patients with RHD, the association of HLA-DR7 with some DQ-A or DQ-B alleles, both encoded by the *HLA-DQ* gene, was linked to the development of multiple valvular lesions.[46,47] In Japanese patients with RHD, susceptibility to mitral stenosis seems to be controlled in part by the *HLA-DQA* gene or by genes in

close linkage disequilibrium with some HLA-DQA and DQB1 alleles.[49] An RHD cohort consisting of a Mexican Mestizo population displayed an association between HLA-DR2 and some DQA and DQB alleles.[39]

CTLA-4 is a protein that plays a role in the adaptive immune response as a negative regulator of T cell proliferation. A polymorphism (G/G) in exon 1 of the *CTLA4* gene with an inhibitory function was found in patients with RHD.[50]

Inflammatory and anti-inflammatory cytokines play a role in both innate and adaptive immune responses and are also involved in the development of RF tissue lesions.

The *IL1* gene cluster located on chromosome 2 includes the genes expressing the pro-inflammatory cytokines IL-1a and IL-1b and their inhibitor IL-1 receptor antagonist (IL-1ra). The absence or misrepresentation of two alleles of VNTR from the *ILRA* gene results in a strong inflammatory response. Patients with RHD who have severe carditis display low frequencies of one of these alleles, suggesting an absence of inflammatory control.[51,52]

The *TNF* gene encodes the inflammatory cytokine TNF, which contributes to the development of valvular lesions. An association of *TNF* polymorphisms with RF and RHD has been shown in four independent studies.[53-56]

The anti-inflammatory cytokines IL-10 and transforming growth factor (TGF)-β are produced by activated immune cells, especially monocytes/macrophages and T cell subsets including regulatory T cells (Tr1 and Treg) and Th1 cells.[57] The development of multivalvular lesions is associated with some polymorphisms in the promoter regions of the *IL10* and *TGFB1* genes[51,52] and with the severity of RHD lesions.

The roles of these genes are to drive the immune response against infection, and as previously described, they lead to a predisposition of developing the disease. The major mechanisms leading to autoimmune reactions are discussed in the next section.

## Pathologic Effector Mechanisms and Autoimmunity

As previously mentioned, recurrent attacks of ARF lead to tissue damage that can affect the joints, heart, and brain in people who have susceptibility genes. Both humoral and cellular immune reactions are effectors of the autoimmune reactions that follow *S. pyogenes* infection, and the phenotype of the disease is under genetic control and depends on factors such as age and episodes of recurrence, as previously mentioned.

Diverse biologic mechanisms such as immune complex formation, molecular mimicry, and epitope spreading are involved in the development of autoimmune reactions in RF and RHD. To aid the reader, we briefly define the mechanisms followed by their implications in the pathologic process.

### Immune Complex

The generation of immune complexes occurs through the interaction between antigen and specific antibodies and facilitates the clearance of foreign antigens by phagocytic cells.

### Molecular Mimicry and Epitope Spreading

The molecular mimicry mechanism takes into consideration the existence of similar or identical antigens in microbes (viruses, bacteria, and other pathogens) and their hosts. This mechanism enables the microbe to evade the host immune response and facilitates the recognition of self-antigens after an infection by cross-reactivity. Both T and B lymphocytes can recognize pathogens and self-antigens through molecular mimicry by four different types of mimicry. They can recognize (1) identical amino acid sequences, (2) homologous but nonidentical sequences, (3) common or similar amino acid sequences of different molecules (proteins and carbohydrates), and (4) structural similarities between the microbe or environmental agent and its host.[58]

Diversification of the immune response against an immunodominant epitope from a pathogen, human tissue, or soluble protein leads to its amplification and has been defined as epitope spreading.[59] This process favors the recognition of several self-antigens and facilitates tissue damage in different organs.

The major manifestations of disease result from interactions between these mechanisms.

### Arthritis

In the joints, anti-streptococcal antibodies—likely against group A carbohydrates, components of the bacterial cell membrane, or the M protein—precipitate to form immune complexes and activate the complement cascade to induce transitory arthritis.[60]

### Sydenham's Chorea

The pathogenic mechanism leading to the development of Sydenham's chorea was clarified by Kirvan et al.[24,61] Briefly, these investigators showed that antibodies from the sera of patients with chorea were able to bind to neuronal cells. They also identified gangliosides as autoantigens that cross-react with N-acetyl-β-D-glucosamine, the major cell wall streptococcal antigen, and showed that autoantibodies mediate signal transduction by calcium/calmodulin-dependent protein kinase II, triggering dopamine release from neuronal cells.

### Rheumatic Heart Disease

Sera antibodies from patients with RF simultaneously recognize N-acetyl-glucosamine, a streptococcal carbohydrate antigen, and specific regions of cardiac myosin in the myocardium and tropomyosin and laminin in the valves.[62] These cross-reactive antibodies may bind to the valvular endothelia and basement membrane, generating inflammatory signals that may upregulate the expression of several adhesion molecules, facilitating lymphocyte extravasation into the valve. The expression of vascular cell adhesion molecule (VCAM)-1, an adhesion molecule present in the vascular endothelium, is activated after initiation of an inflammatory reaction by anti-myosin and N-acetyl-glucosamine antibodies. These molecules interact with very late activation antigen (VLA)-4, another adhesion molecule

expressed on $CD4^+$ T lymphocytes, and facilitate its infiltration into the heart tissue.[62] Recently we verified that intercellular adhesion molecule (ICAM), another adhesion molecule, as well as the integrin P-selectin and several chemokines and their receptors, were upregulated. Among the chemokines, the gene expression of CCL3/MIP1α was upregulated in the myocardium, whereas CCL1/I-309 and CXCL9/Mig were highly expressed in the valvular tissue of patients with RHD.[63] An in vitro assay demonstrated that valvular lesions infiltrating T cells migrated mainly toward a CXCL9/Mig gradient, suggesting that specific chemokines can mediate both $CD4^+$ and $CD8^+$ T cell infiltration to the site of inflammation in the heart.[63] Several cytokines contribute to the inflammatory process and cellular infiltration. These data are summarized in Table 115-2.

Cardiac myosin is the major antigen in the myocardium. Using affinity-purified anti-myosin antibodies, Cunningham et al.[64] identified an epitope of the N-terminal M5 and M6 proteins consisting of a five-amino acid residue (Gln-Lys-Ser-Lys-Gln) that cross-reacted with cardiac myosin.

Human heart intralesional T cells obtained from valve tissue from patients with RHD who underwent surgery for valve correction allowed evaluation of in vitro reactivity against heart-tissue proteins[65] and human light meromyosin (LMM)[66] streptococcal M5 peptides and mitral valve–derived proteins. The frequency of intralesional T cell clones that recognized LMM peptides was 63.2%. Thirty-four percent of the T cell clones presented different patterns of cross-reactivity: i, myosin and valve-derived proteins; ii, myosin and streptococcal M5 peptides; and iii, myosin, valve-derived proteins, and M5 peptides. In addition, it has been recognized that several LMM peptides simultaneously display multiple reactivity patterns in heart-infiltrating T cells and also against peripheral T cells of patients with RF/RHD.[67] The high percentage of reactivity against cardiac myosin strengthens its role as one of the major autoantigens involved in rheumatic heart lesions. T cell reactivity toward myosin epitopes in patients with RHD may also trigger the broad recognition of valvular proteins with structural or functional similarities.

Valvulitis follows myocarditis, and the mitral and aortic valves display the most damaged tissue. Similarities between N-acetyl-β-D-glucosamine, a polysaccharide present in both the streptococcal cell wall and heart valve tissue, are probably responsible for the autoimmune reactions, as suggested by the observation that antibodies against N-acetyl-β-D-glucosamine display cross-reactivity with laminin, an extracellular matrix α-helical coiled-coil protein that surrounds heart cells and is also present in valves.[62]

Vimentin, a structural protein that plays diverse roles, is important for the binding and stabilization of collagen messenger RNAs. In vitro, this protein has been detected by a proliferation assay in both peripheral blood and heart tissue–infiltrating T cells from patients with RHD, reinforcing its role as a putative target antigen of autoimmune rheumatic lesions.[65,68]

Recently, an evaluation of the protein profile of valvular tissue from patients with RHD based on two-dimensional electrophoresis and mass spectrometry analyses showed an imbalance of heart tissue protein expression, probably as a result of the autoimmune reactions that follow streptococcal infection. Briefly, several proteins displayed an elevated expression, including vimentin, lumican, and apolipoprotein-A1, whereas collagen-VI, haptoglobin-related protein, prolargin, biglycan, and cartilage oligomeric matrix protein had a reduced expression level.[69]

The prediction of protein interactions in valve damage has also been evaluated by in silico analysis. Among the interactions, the potential roles of TNF, an inflammatory cytokine, and TGF-β (anti-inflammatory) and metalloproteinase (MMP-25) were noteworthy.[69] MMP-25 is involved in matrix degradation, as previously described,[70] and probably also plays an important role in valve damage.

Table 115-3 summarizes the major events described herein leading to RF, Sydenham's chorea, and RHD.

## Cytokines and the Inflammatory Process

Cytokines are also key players in the inflammatory process during RF episodes and later in RHD heart lesions.

Four subsets of Th cells (Th1, Th2, Th17, and Tregs) are currently described. Cytokines are soluble mediators that regulate cell proliferation, differentiation, and survival. Antigen-activated $CD4^+$ T cells polarize to these subsets, depending on the cytokine secreted.

**TABLE 115-2** Molecules Recruiting and Expanding Immune Cells into Heart Tissue

Th1 cells are involved in the cellular immune response and produce IL-2, interferon (IFN)-γ, and TNF. Th2 cells mediate humoral and allergic immune responses and produce IL-4, IL-10, IL-5, and IL-13. Th17 cells are important for protection against bacterial and fungal infections and in the development of autoimmunity. This lineage is induced by TGF-β, IL-6, and IL-23 and secretes IL-17 to mediate a type of pro-inflammatory response.[71]

Tregs, a subset of cells that regulate the inflammatory and autoimmune process, are identified as $CD4^+CD25^+CD127^-CD45RO^+FoxP3^+$ T cells and display immunosuppressive activity.[72]

The roles of cytokines in both RF and RHD have been evaluated in the peripheral blood and in heart tissue lesions. Briefly, in patients with ARF and active RHD, increased production of IL-2 and elevated numbers of $CD4^+CD25^+$ cells have been observed, suggesting the expansion of activated $CD4^+$ T cells in the peripheral blood,[73] as well as increased plasma levels of TNF.[74-76]

The Th1/Th2 cytokine pattern of infiltrating mononuclear cells in the mitral valve and myocardial tissue in patients with ARF and chronic RHD reveal large numbers of IFN-γ and TNF-secreting mononuclear cells. Mononuclear cells secreting IL-10 and IL-4 (regulatory cytokines) were also found in the myocardial tissue, whereas in the valvular tissue, only a few cells secreted IL-4. These low numbers of IL-4–producing cells may contribute to the progression of valvular RHD lesions.[77] Recently, we identified large numbers of IL-17 and IL-23–producing cells in the valves. These cytokines belong to the Th17 subset of cytokines, which are frequently involved in the development of autoimmune diseases, as previously mentioned. In agreement with these data, a Turkish RHD cohort study recently reported increased numbers of Th17 cells in peripheral blood that correlated with IL-17A cytokine levels in the sera and decreased numbers of Tregs.[78]

## Diagnostic Tests

No single laboratory test can confirm the diagnosis of ARF. In a patient in whom ARF is suspected, the workup aims to detect evidence of recent streptococcal infection, documenting the presence or persistence of inflammation, and diagnosing and following the course of carditis.

### Throat Cultures

A rayon-tipped throat culture swab obtained by sampling the tonsils and back of the throat is the current gold standard for the diagnosis of GAS pharyngitis. Nevertheless, when ARF symptoms are present, approximately 75% of patients have negative throat culture findings.[21] A positive throat culture finding may be due to a new infection or to convalescent carriage of the rheumatogenic strain.

### Rapid Antigen Testing

Rapid antigen testing (RSAT) has a high specificity (≥95%) but a moderate sensitivity (65% to 90%).[79] A positive RSAT finding is useful in establishing a diagnosis of GAS pharyngitis, but a negative RSAT finding does not exclude it. In high-risk ARF locations, where high-stake decisions are being made, rapid antigen detection tests (RADTs) are not currently recommended.[80] If an RADT is used and is negative, additional costs are incurred because a follow-up throat swab is required.

### Streptococcal Antibody Tests

Antibody tests are directed against the extra-cellular products of streptococci and include anti-streptococcal lysine O (ASO), anti-DNAse B (ADB), anti-hyaluronidase, antinicotinamide adenine dinucleotidase, and anti-streptokinase. ASO and ADB are the most commonly available tests. ASO begins to rise at 1 week and peaks at 3 to 5 weeks after infection. It begins to decline after approximately 6 to 8 weeks, at a faster pace during the immediate subsequent months, and at a slower pace after 6 months. ADB begins to rise at 2 weeks and peaks at 6 to 8 weeks after infection. It begins to decline approximately 3 months after the precipitating infection. Antibody peaks normally coincide with the second or third week of ARF. Patients will have elevated ASO and ADB titers 80% and 85% of the time, respectively, when symptoms of ARF are present. When both ASO and ADB tests are conducted, 92% of patients will have abnormal test results.[81] The antibody tests must be interpreted with caution in areas with high rates of streptococcal infection and ARF because relatively high titers are commonly encountered in such populations. A second sample should be collected 2 weeks later to characterize a recent infection based on a significant rise in antibody titers. Asymptomatic pharyngeal streptococcus carriers usually have titers that are just above detectable, and therefore a high titer indicates a true infection. Increases in ASO occur not only in response to GAS infections but also in infections with groups C and G streptococci and other bacteria such as bacillus, *Clostridium tetani*, and *Listeria monocytogenes*.

### Acute-Phase Reactants

Acute-phase reactants, the erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) levels rise during an ARF attack, with the exception of chorea or erythema marginatum as a single manifestation. Acute-phase reactants aid in monitoring the evolution of inflammation and serve as minor manifestations based on the Jones criteria. Salicylates or other NSAIDs may mask the results of these tests. ESR may stay elevated for up to 2 months after an inflammation, whereas CRP normalizes within days.

### Other Laboratory Tests

Transient and asymptomatic abnormalities of liver function tests, bilirubins, and a mild normochromic normocytic anemia are observed in a significant portion of patients with ARF and usually normalize after cessation of inflammation. Blood cultures should be obtained to help rule out infective endocarditis, bacteremia, and disseminated gonococcal infection.

Depending on the clinical features, additional tests should be performed to rule out an alternative diagnosis, such as anti-nuclear antibody and head magnetic resonance assessments.

### Chest Radiography

If myocardial dilatation and/or pericardial effusion are significant, a chest radiograph may reveal an enlarged heart silhouette. Pulmonary edema may be observed in the presence of HF.

### Electrocardiography

Tachycardia and prolongation of the PR interval are the most common electrocardiographic findings of myocarditis. Rarely, third-degree heart blockage may be observed. Pericarditis can induce a diffuse elevation of the ST segments. Electrocardiographic abnormalities are present in approximately 21% of patients, 60% of whom have degrees of heart blockage.

### Echocardiography

Echocardiography is 10 times more sensitive than auscultation in identifying valvular involvement,[82] and the use of echocardiography results in a 16% to 47% increase in the diagnosis of carditis.[83] Echocardiography confirms the clinical findings for valvular lesions objectively, addresses progression, and helps dismiss nonrheumatic causes of valvular damage. Nevertheless, echocardiography was not included in the 2004 WHO criteria for the diagnosis of RF.[21] This decision was driven by concern that the diagnosis could be hampered by the lack of availability of echocardiographs in some locations and because the evolution of most cases of subclinical carditis is benign.[84]

The long-term follow-up of subclinical carditis diagnosed in patients with a previous or current history of ARF is better characterized than subclinical carditis in asymptomatic populations. In the first group, valve lesions persist in 30% of patients after 5 years, and half of the patients diagnosed with subclinical carditis at the time of ARF show persistence or deterioration of their carditis during the ensuing 2 years.[83] As a result, the New Zealand (NZ) and Australia (AU) criteria for RF diagnosis include subclinical carditis as a major criterion for the diagnosis of ARF in high-risk people and recommend that all patients with suspected or confirmed ARF undergo echocardiography.[85,86,87]

Subclinical RHD may be defined as features of RHD on echocardiography in the absence of symptoms and signs of heart valve disease. Studies reporting the short-term progress of subclinical RHD detected by echocardiography suggest that the severity of subclinical RHD is not progressive in 68% to 69% of children, whereas it worsens in 4% to 9% and regresses in 28% to 32% of children.[84] This evolution is similar to that observed in auscultation-only screening programs[86] and indicates that the spontaneous resolution of changes will take place in 30% to 40% of suspected RHD cases that are detected by either auscultation or echocardiography in asymptomatic populations. Techniques to identify "persistors and progressors" who may be eligible for secondary prophylaxis are lacking. Preliminary studies suggest that disease classified as definite by echocardiography (i.e., with morphologic and functional changes) is more likely to persist than are borderline or possible categories (with either minor morphologic or functional changes).[86] The additional costs and excess of people receiving treatment as a result of RHD screening protocols would be justifiable if the prognosis of RHD improved; however, it has not yet been demonstrated that penicillin prophylaxis for all children with subclinical rheumatic valve lesions is the best option in clinical practice. The question remains unanswered; however, some specialists consider these screening programs to be cost-effective in areas with a high prevalence.[88,89]

A standardized evidence-based guideline for the echocardiographic diagnosis of RHD has been developed by the World Heart Federation to improve the reliability, comparability, and reproducibility of echocardiographic screening studies.[89] It should be used to follow up on subclinical lesions to evaluate the progression of RHD and recurrences of ARF. It is envisioned that the new guideline may reduce the potential for overdiagnosis of RHD in screening studies by excluding physiologic valve regurgitation and congenital valve anomalies that may be present in at least 1% of normal children.[84]

## Diagnosis

The manifestations of ARF, as with its incidence, vary notably in frequency and intensity among different age groups, individuals, and localities.[7] The sensitivity and specificity of any criteria depend on the incidence of the disease and thus have the same variation. This phenomenon is relevant because there are no specific diagnostic tests for ARF, and a diagnostic mistake has severe consequences. The classic Jones criteria was first published in 1944 and revised in 1965 and 1992. In 2004, the WHO published an expert consultation report that included ARF criteria based on the previous revised Jones criteria (Table 115-4). Each criterion modification has resulted in more specific and less sensitive criteria, which is appropriate for most of the developed world but not for hot spots. NZ[85] and AU[86] have developed their own criteria, the main particularities of which are the use of echocardiograms for the diagnosis of carditis, aseptic monoarthritis as a major criterion (provided NSAIDs are used in NZ and only for high-risk individuals in AU), the use polyarthralgia as a major criterion for high-risk individuals (AU) and monoarthralgia as a minor criterion for high–risk individuals (AU). Utilization of NZ guidelines for the diagnosis of ARF result in a modest increase (16%) in cases classified as definite ARF compared with the American Heart Association (AHA) 1992 Jones criteria.[83] These guidelines may be more applicable to high-risk populations.

## Treatment

### Primary Prophylaxis

Adequate treatment of streptococcus pharyngitis reduces the likelihood of the subsequent development of ARF.[90] Nevertheless, streptococcus cannot be differentiated from other pharyngeal pathogens on a clinical basis, cultures take days to provide results, and RSAT lacks sensitivity and adds costs. The majority of sore throats are viral in origin. Fifteen percent to 30% of sore throats in children and 10% in adults are estimated to be due to GAS.[83] Whether all pharyngeal

**TABLE 115-4** 2004 World Health Organization Criteria for the Diagnosis of Rheumatic Fever and Rheumatic Heart Disease

| Diagnostic Categories | Criteria |
|---|---|
| Primary episode of RF[a] | 2 major* or 1 major and 2 minor** manifestations plus evidence of a preceding group A streptococcal infection*** |
| Recurrent attack of RF in a patient without established RHD[b] | 2 major or 1 major and 2 minor manifestations plus evidence of a preceding group A streptococcal infection |
| Recurrent attack of rheumatic fever in a patient with established RHD | 2 minor manifestations plus evidence of a preceding group A streptococcal infection[c] |
| Rheumatic chorea and insidious onset of rheumatic carditis[b] | Other major manifestations or evidence of group A streptococcal infection are not required |
| Chronic valve lesions of RHD (patients presenting for the first time with pure mitral stenosis or mixed mitral valve disease and/or aortic valve)[d] | Do not require any other criteria to be diagnosed as having RHD |
| *Major manifestations | Carditis, polyarthritis, chorea, erythema marginatum, subcutaneous nodules |
| **Minor manifestations | Clinical: fever, polyarthralgia; Laboratory findings: elevated acute-phase reactants (ESR or leukocyte count) |
| ***Supporting evidence of: electrocardiogram | Prolonged PR interval; preceding streptococcal infection; elevated or rising anti-streptolysin-O or streptococcal infection with another streptococcal antibody; infection in the past 45 days; a positive throat culture; rapid antigen test for group A streptococci; recent scarlet fever |

[a]Patients may present with polyarthritis (or with only polyarthralgia or monarthritis) and with several (three or more) other minor manifestations, together with evidence of recent group A streptococcal infection. Some of these cases may later turn out to be rheumatic fever. It is prudent to consider them as cases of "probable rheumatic fever" (once other diagnoses are excluded) and advise regular secondary prophylaxis. Such patients require close follow-up and regular examination of the heart. This cautious approach is particularly suitable for patients in vulnerable age groups in high-incidence settings.

[b]Infective endocarditis should be excluded.

[c]Some patients with recurrent attacks may not fulfill these criteria.

[d]Congenital heart disease should be excluded.

ESR, Erythrocyte sedimentation rate; RF, rheumatic fever; RHD, rheumatic heart disease.

Data from the revised Jones criteria.[21]

infections should be treated a priori with antibiotics strongly depends on the incidence of ARF in the evaluated population. The case of Costa Rica is often used by those who advocate the use of antibiotics for all sore throat cases in locations with a high incidence of ARF. This policy was instituted in Costa Rica in 1970, and the number of new cases of ARF fell from 94 new cases in that year to only 4 in 1991.[90] A similar decrease in ARF incidence occurred in Europe and in the United States before the availability of antibiotics, and critics attribute the decrease observed in Costa Rica, at least in part, to other socioeconomic improvements, including housing conditions, education, and health care access. NZ long ago introduced an efficient program of close surveillance and optimized treatment of pharyngitis for its high-risk populations, but to date, these measures have not been successful in reducing the incidence of ARF.[91] This outcome could be related to the observation that approximately half of streptococcus pharyngeal infections can be asymptomatic[8] and that only a small portion of patients with a sore throat will seek medical attention.[8] The NZ and AU Guidelines for sore throat management do not indicate throat swabs or antibiotics for low-risk people with mild symptoms, provided there is a low occupational risk of spreading GAS. People with a high risk of developing ARF should have a throat culture and be treated if positive results are obtained or should receive empiric antibiotics if follow-up is a concern.[82]

## Acute Rheumatic Fever Treatment

**Eradication of Streptococcus.** Immediate eradication of streptococcus is a standard practice for patients presenting with ARF, even before throat culture results are obtained. Although an improvement of 1-year outcomes was never demonstrated, it is conducted with the goal of minimizing prolonged exposition to the trigger factor and of reducing the spread of rheumatogenic strains. Household contacts should also have throat cultures, and people with positive results should be treated even if they are asymptomatic.[85]

**Acute Carditis.** The extent of acute cardiac involvement is probably the most important event in determining the long-term morbidity and mortality of RF. Nevertheless, currently no effective therapies have been demonstrated to alter the natural history of the disease.[92] Illingworth and colleagues reviewed 170 articles and concluded that aspirin was not beneficial in the treatment of acute carditis.[92] This finding was reiterated by a United Kingdom–United States joint report in 1955.[92] Studies of corticosteroid therapy for the treatment of ARF were performed largely in the 1950s and 1960s, before the availability of echocardiography. In 1995, a meta-analysis involving more than 130 studies concluded that corticosteroids were not statistically superior to salicylates in preventing a pathologic murmur at 1 year after treatment, and inflammation tended to recur once steroid therapy was withdrawn. However, given that the confidence intervals were wide and that there was significant heterogeneity in the results between these studies, the authors indicated that the precision of this meta-analysis was not high, and therefore marginal improvements may have been overlooked.[93] Three Cochrane reviews have been published on this subject, and similar conclusions were drawn.[94] Additionally, the clinical parameter used by the referenced studies does not allow accurate inferences about the severity of heart damage. As a result, doubt persists, and corticosteroids are still widely used to treat acute carditis worldwide. A new multicentric randomized clinical trial (Steroids in Acute Rheumatic Fever [STERARF]) is currently under way.

In the NZ and AU guidelines, glucocorticoids are indicated as optional for severe cases of carditis.[84,85] The 2004

WHO expert consultation panel recommended the use of corticosteroids for patients with pericarditis (HF) who do not respond to salicylates and continue to worsen and experience HF despite anti-inflammatory therapy. Prednisone (1 to 2 mg/kg per day to a maximum of 80 mg/day, administered once daily or in divided doses) is usually the drug of choice.[21] After 2 to 3 weeks of therapy, the dosage may be diminished weekly by 20% to 25%. Investigators who conducted two additional recent, small, randomized clinical trials[95,96] investigating the use of intravenous methylprednisone for the treatment of active rheumatic carditis have obtained inconsistent findings on the advantage of intravenous compared with oral corticosteroid therapy for valvular outcomes. Nevertheless, both the WHO and NZ/AU Guidelines recommend intravenous methylprednisolone in life-threatening circumstances. Salicylates or other NSAIDS may need to be resumed after discontinuation of glucocorticoids to avoid rebound joint symptoms or fever.

IVIG was evaluated prospectively in a randomized clinical trial involving 59 patients with ARF (39 of whom had carditis), and it was found that the treatment did not alter the natural history of ARF. No differences were observed in the clinical, laboratory, or echocardiographic parameters of the disease process during the 12 months of follow-up.[97]

Bed rest is traditionally advised, although this recommendation is not based on clinical trial results. In the prepenicillin era, it was associated with a shorter duration of carditis, fewer relapses, and less cardiomegaly.[98] Patients with mild or no carditis should avoid ambulation only as necessary to avoid joint pain. Persons with severe carditis are advised to rest, especially during the first 4 weeks or until serum CRP levels have normalized and the ESR has normalized or significantly diminished.[85]

**Heart Failure.** Although CHF is more frequent during recurrences, it also occurs in 5% to 10% of initial ARF episodes. If bed rest and steroids are not sufficient to manage HF, it must be treated early and aggressively with diuretics and a diet with restricted sodium content. Angiotensin-converting enzyme inhibitors and digoxin may also be used. Few studies have evaluated treatment with β-blockers in people with HF due to acute carditis, and currently the use of these treatments is not recommended.[85] Second- and third-degree heart blockages may require a transient pacemaker.

**Emergency Valve Surgery.** Surgery should be deferred until active inflammation has subsided, but the rupture of a valve leaflet or chordae tendineae may lead to severe regurgitation and the need for emergency procedures. During the acute phase, valve replacement is usually preferred compared with repair of the friable inflamed valve.[85]

**Arthritis and Fever.** Arthritis and fever often respond to NSAIDs within hours and almost always within 3 days. If not, the diagnosis should be challenged. Aspirin (80 to 100 mg/kg per day in children and 4 to 8 g/day in adults) is traditionally used and should be continued until all symptoms subside and inflammatory markers normalize. Most patients will need to take NSAIDs for only 1 to 2 weeks; however, some will need NSAIDs for up to 6 weeks, and in approximately 5% of cases, 6 months or more of salicylate therapy is required.[85] The use of other NSAIDs is a possibility, and naproxen has been reported to be effective and well tolerated. NSAIDs alter acute-phase reactants, and thus therapy for ARF manifestations should be withheld if the diagnosis is uncertain. In such cases, paracetamol can be used. The recurrence of joint symptoms during NSAID withdrawal does not indicate ARF recurrence and can be treated with another brief course of high-dose NSAIDs.

**Chorea.** Chorea is often self-limited and mild and does not require specific treatment aside from rest and a calm environment. In prolonged or incapacitating cases, neuroleptics, diazepam, and anti-convulsant agents have been reported to be effective. Aspirin and glucocorticoid therapy do not influence this manifestation. A prospective comparison of carbamazepine, valproic acid, and haloperidol in 18 patients with chorea concluded that valproic acid was the most effective treatment.[99] A reduction but not an eradication of symptoms should be expected after 1 to 2 weeks of therapy. Medication should be continued for 2 to 4 weeks after chorea has abated.

## Rheumatic Heart Disease Management

In 2014, the American College of Cardiology (ACC) and the AHA published an update of their former 2008 AHA/ACC guidelines for the management of patients with valvular heart disease (VHD).[100] The focus of this guideline is the diagnosis and management of adult patients with VHD through a combination of lifestyle modifications, medications, and medical procedures.

## Secondary Prophylaxis

Patients with RF are at a high risk for recurrences and progression of the severity of manifestations following a new GAS infection. Because streptococcal pharyngitis is often asymptomatic, prevention requires continuous antimicrobial prophylaxis rather than treatment of acute GAS pharyngitis episodes. Continuous administration of benzathine penicillin G (BPG) reduces the chances of a new streptococcal pharyngitis in 71% to 91% of cases, the chances of a new episode of ARF in 87% to 96% of cases, and the severity of RHD[102] and its associated mortality.[103]

Secondary prophylaxis is indicated for all patients with a documented history of ARF, Sydenham's chorea, or convincing evidence of RHD.

Intramuscular penicillin is more effective than oral penicillin in preventing recurrences.[101] BPG is indicated at 1.2 million units by intramuscular injection for people weighing more than 27 kg (60 lb) and 600,000 units for people weighing less than 27 kg[21] (20 kg in NZ/AU guidelines).[84,85] Serum penicillin levels may be undetectable or low 28 days after a 1,200,000-unit BPG dose.[104] For high-risk patients, intramuscular BPG injections every 3 weeks should be considered. Patients treated with this regimen exhibit fewer streptococcal infections and ARF recurrences[85,102] and a greater resolution of mitral regurgitation over the long term.[104] Nevertheless, prospective data from NZ showed that recurrences were rare (0.07 per 100 patient years) among patients who were fully adherent to a four-weekly BPG regimen, which is the current recommendation in the United States.

If an intramuscular route is not possible or refused, the second-line regimen is oral penicillin V, 250 mg twice

daily. Patients with a documented allergy to penicillin should receive oral erythromycin, 40 mg/kg (maximum of 1 g/day) daily divided into two to four doses for children and oral erythromycin, 400 mg twice daily for adults and adolescents.[21,85,86]

Secondary prophylaxis should last until the risk of ARF recurrence is irrelevant, and thus the discontinuation time should be individualized. Guidelines from the WHO, NZ, and AU Guidelines were developed on the basis of their respective data and differ slightly. In the NZ environment, maintenance of prophylaxis up to 21 years of age is considered safe and effective in cases with absent or mild heart disease.[85] In a review of data from the 1993-1999 Auckland (NZ) Acute Rheumatic Fever Register, only five recurrences occurred after the age of 30 years. Data from the Northern Aboriginal Territory of Australia showed that only approximately 1% of 259 ARF episodes recorded between 2005 and 2009 occurred after 40 years of age. Therefore, 30 and 40 years of age were considered the most reasonable cutoffs to cease secondary prophylaxis for patients with severe carditis in NZ and AU, respectively. In both countries, exceptions are made for individual circumstances warranting continuing prophylaxis (e.g., patients wanting to reduce even a small chance of a recurrence).

It is not clear whether these prophylaxis regimens should be followed in sporadic cases in locations with a low incidence of ARF, because these regimens have been largely developed in regions where ARF remains a significant burden. In a prospective study in modern Chile, 59 patients with ARF who were judged to be at a low risk for recurrences were permitted to receive no secondary prophylaxis. During the 3349 patient-months of follow-up, only two ARF attacks were observed, and the authors suggested that ARF prophylaxis could be discontinued safely in patients with a low risk of recurrence who undergo careful prospective surveillance.[105]

The efficacy of secondary prophylaxis depends completely on compliance. In a prospective international study involving 1790 patients, a prevalence of new ARF attacks was observed in 0.45% of the compliant patients compared with 11.5% of noncompliant patients.[106] Only one in five patients with RF from Aborigine communities of Australia received 80% or more of the scheduled doses.[107] Reasons for failed compliance were painfulness and a high frequency of injections, a long treatment period, and low socioeconomic and educational levels of the patients.

### Infective Endocarditis Prophylaxis

Infective endocarditis (IE) is a potentially lethal complication of RHD. Antibiotic prophylaxis prior to procedures has not been proven effective in preventing IE but is supported by animal models, empirical observations, and expert opinion.[86] All patients with RHD or prosthetic valves should receive IE antibiotic prophylaxis prior to dental procedures and other procedures expected to produce bacteremia. People with a history of ARF but no valvular damage do not require endocarditis prophylaxis. Transesophageal echocardiogram, esophagogastroduodenoscopy, colonoscopy, and cystoscopy are examples of procedures that do not require IE prophylaxis in the absence of active infection. For people receiving secondary prophylaxis for RF, a different antibiotic should be offered. Guidelines aimed at the optimal diagnosis and management (including prophylaxis) of IE are offered and constantly updated by specialized institutions.[101]

## Vaccine Development

Although RHD control programs have been implemented around the world, the disease remains a health problem in several countries. The epidemiologic growth of streptococcal diseases in undeveloped and developing countries has encouraged many groups to study vaccine candidates for the prevention of GAS infections.

The development of a vaccine against *S. pyogenes* would provide many benefits such as preventing streptococcal infections and their sequelae. Several vaccine development studies have been proposed in previous decades with no satisfactory results.

After the introduction of new methodologies, such as the synthesis of peptides and molecular biological techniques, some proposals have been under development for the past 20 to 25 years.

Four anti-GAS vaccine candidates target the M protein, and eight other candidates target alternative streptococcal antigens, including group A-CHO, C5a peptidase (SCPA), cysteine protease (Spe B), binding proteins similar to fibronectin, opacity factor, lipoproteins, Spes (super antigens) and streptococcal pili, as reviewed by Steer et al.[108]

Strain-specific vaccines based on recombinant N-terminal portions of the M protein serotypes that are most prevalent in the United States were entered into phase I/II clinical trials and, currently, a new approach based on the 30 most prevalent serotypes is being investigated in a phase I clinical trial.[109]

Two other promising vaccines incorporate C-terminal protective epitopes and differ with respect to their mechanisms of action. One is based on a minimal protective epitope that induces protective antibodies,[110-112] and the other is a long peptide (55 mers) identified as StreptInCor.[113] The advantage of the StreptInCor vaccine model is the possibility of the vaccine epitope undergoing processing by antigen-presenting cells (monocytes and/or macrophages) to generate several peptides that induce both B and T immune responses, resulting in a safe and robust immune response.[114] Experimental assays have demonstrated that the StreptInCor peptide induces high titers of opsonic and neutralizing and protective antibodies in outbred immunized mice.[115,116] Using class II HLA transgenic mice, it was possible to evaluate the immunogenicity and safety of the StreptInCor vaccine epitope for a period of 1 year. Specific and nonautoreactive antibodies were produced. No autoimmune or pathologic reactions were observed in the heart or other organs.[117]

Considering all the vaccine development approaches in progress, a safe and protective anti–*S. pyogenes* vaccine may be achieved within the next 5 years.

# POST-STREPTOCOCCAL ARTHRITIS

According to the current definition of reactive arthritis, only infections that affect the gastrointestinal or genitourinary tract are associated with this diagnosis.[118] However, the

GAS and *Chlamydophila pneumoniae* agents that affect the respiratory tract have also been implicated in reactive immune-mediated aseptic arthritis. Another disputed question is whether post-streptococcal reactive arthritis (PSRA) should be considered an atypical and incomplete form of ARF or a separate disease. The small number of available publications are predominantly based on small sample sizes and are hampered by a generally accepted definition of PSRA. These case series have suggested significant dissimilarities between the two conditions. Whereas ARF affects mainly children aged 4 to 9 years, PSRA seems to have a bimodal age distribution with peaks between 8 and 14 years and between 21 and 37 years.[118,119] RF symptoms commence 2 to 3 weeks after the streptococcal infection, whereas in PSRA, the latency period is only approximately 10 days. Arthritis in PSRA is often additive and symmetric. Knee and ankle joints are normally involved, but small joint and axial involvement also occurs. In PSRA, the mean duration of arthritis is approximately 2 months, but subsequent arthralgia may persist for 3 years. In up to 19% of patients, arthritis recurs after an interval of a few months. The response to salicylates and other NSAIDs is dramatic in people who have arthritis associated with ARF but less convincing in people with PSRA.[120]

A retrospective series involving 26 patients demonstrated that polytendinitis, tenosynovitis, and enthesitis are common presentations in PSRA and can be the only manifestation.[120] This finding, and the possibility of axial involvement, raises suspicion that what is currently known as PSRA is truly a heterogeneous group of disorders, with some disorders sharing features of spondyloarthropathies and other disorders being more similar to ARF. An animal model of rheumatoid arthritis may facilitate our understanding of this heterogeneity. In this model, rats are treated via intraperitoneal injection of streptococcus cell walls fragments, which are highly resistant to biodegradation. Within 24 to 48 hours of administration, complement-dependent acute inflammation develops in the peripheral joints of the animal together with dissemination of cell wall fragments in the blood vessels of the synovium and subchondral bone marrow. In some rats, the initial inflammation subsides; in others, it persists, or it subsides and recurs. The chronic, T cell–dependent erosive polyarthritis that affects some rats is believed to be initiated by an inflammatory process promoted by macrophages struggling to degrade the cell wall fragments. Chronic joint inflammation develops only in susceptible rats but is not dependent on specific streptococcus strains. Remarkably, chronic arthritis will not develop in rats raised in a germ-free environment, suggesting that streptococcus cell wall fragments do not elicit a specific autoimmune reaction but instead function as an adjuvant, promoting other cross-reactive immune processes involving other bacteria, perhaps in the gastrointestinal or genitourinary track. It is possible that in PSRA, the streptococcus infection has a similar adjuvant rule, promoting only an established autoimmunity. In such a case, the different clinical pictures of the PSRA spectrum would follow the different individual susceptibilities.

The most important practical question to be answered is whether patients with PSRA have an increased risk of RHD and require secondary prophylaxis. Three echocardiography-based studies in children with PSRA provided evidence of cardiac involvement in 6 of the combined number of 76 patients. Adults with PSRA were shown to be free of valvular abnormalities by echocardiographic screening in two case series and in one prospective study involving 75 patients who did not receive antibiotic prophylaxis and were followed up for almost 9 years.[118] Because the present literature on PSRA is mainly based on American and western European patients, the conclusions may not be applicable to people in other parts of the world. The WHO ARF guidelines state that "patients with arthritis following a streptococcal upper respiratory infection should be considered to have RF if they fulfill the Jone's criteria." The NZ and AU guidelines recommend that the diagnosis of PSRA rarely, if ever, should be made in high-risk populations and should be made with caution in low-risk populations. In those countries, patients diagnosed with PSRA who are at a high risk of developing ARF should receive secondary prophylaxis for at least 5 years. Low-risk patients should receive this treatment for at least 1 year. An absence of valve involvement should again be confirmed by echocardiography prior to the discontinuation of antibiotics.

## CONCLUSION

The data presented herein demonstrate that several genes play a role in the development of RF, RHD, and PSRA. These genes control both innate and adaptive immune responses. The autoimmune reactivity is due to molecular mimicry between human proteins and antigens of *S. pyogenes*. The M protein is the major antigen of the bacteria and consists of two regions. The polymorphic N-terminal region and differences in the A and B blocks of amino acids define the diverse types of bacteria. The C-terminal region is conserved. Some regions of the block B of the N-terminal region are involved in autoimmune reactions. An imbalance between inflammatory/anti-inflammatory cytokines that are produced in response to the infection leads to acute and chronic inflammation. In addition, the low numbers of Treg cells facilitate increased inflammatory reactivity and consequently chronic disease.

The treatment and prevention of new episodes of RF and RHD are based on penicillin-benzathine as a primary prophylaxis and other drugs, as previously described. The possibility of prevention/treatment by administration of a vaccine against *S. pyogenes* in the near future is also presented.

CHAPTER 116

# Amyloidosis

Ralph C. Budd • David C. Seldin†

**KEY POINTS**

- ***Amyloidosis*** **is the term for systemic disease in which aggregated proteins form extra-cellular fibrils in tissues of the body, eventually leading to organ failure and death if not effectively treated.**
- **Patients with amyloidosis can present with joint symptoms and soft tissue deposits that mimic rheumatologic disorders, and inadequately controlled rheumatologic disease or chronic infection can lead to secondary AA amyloidosis.**
- **The diagnosis of amyloidosis requires a tissue biopsy demonstrating green birefringent fibrils by polarization microscopy after staining with Congo red.**
- **Appropriate treatment depends on accurate biochemical or immunochemical identification of the amyloid type, distinguishing hereditary from acquired forms of amyloidosis.**

The term *amyloidosis* includes diseases that have in common the extra-cellular deposition of insoluble fibrillar proteins in tissues and organs. These diseases are a subset of a growing group of disorders recognized to be caused by misfolding of proteins; they include Alzheimer's and other neurodegenerative diseases, prion diseases, serpinopathies, some of the cystic fibroses, and others. A unifying feature of the amyloidoses is that the deposits share a common β-pleated sheet structural conformation that confers unique staining properties. The name "amyloid" is attributed to the pathologist Virchow, who in 1854 thought that such deposits in livers at autopsy were cellulose because of their peculiar staining reaction with iodine and sulfuric acid.[1] In the 20th century, amyloid was found to be a proteinaceous fibrillar deposit in tissues.[2] Biochemical characterization of fibril proteins from clinical cases have proven the amyloidoses to be diverse diseases, many with a potentially fatal outcome as a result of progressive deposition of amyloid fibrils in major organs. A growing number of treatments are available to target the source of the abnormal protein and, for some types, to inhibit the amyloidogenic protein misfolding process.

## CLASSIFICATION AND EPIDEMIOLOGY

Amyloid diseases are defined by the biochemical nature of the protein in the deposited fibril. The proteins are diverse and are unrelated in primary amino acid sequence, resulting in classification of amyloid diseases according to whether they are systemic or localized and acquired or inherited; their recognized clinical patterns also determine how they are classified (Table 116-1).[3] Each amyloid disease has a shorthand nomenclature, expressed as *A* for amyloidosis and an abbreviation for the biochemical nature of the fibrils; for example, *AL* is amyloid of Ig *light chain* origin. The discussion in this chapter is limited to the systemic amyloidoses because it is these diseases that can involve the joints and are potentially confused with autoimmune rheumatologic disorders.

The acquired systemic amyloidoses are AL (Ig light chain, or primary), AA (reactive, secondary), and $A\beta_2M$ (β2-microglobulin, dialysis-associated) types. The AL type is most common, although epidemiologic data are limited. One study based on National Center for Health Statistics data estimated the incidence as 4.5 per 100,000.[4] AL amyloidosis usually manifests after age 40 years and is associated with rapid progression, multisystem involvement, and short survival. AA amyloidosis is rare, occurring in fewer than 1% of patients with chronic inflammatory diseases in the United States and Europe, but it is more common in Turkey and the Middle East, where it occurs in association with familial Mediterranean fever.[5] As treatments for chronic inflammation and infection improve, the origin of AA amyloidosis appears to be shifting toward rare hereditary periodic fever syndromes or hematologic disorders associated with production of inflammatory cytokines such as Castleman's disease; workup should include genetic testing and imaging to screen for these conditions.[6] The onset of AA amyloidosis is variable and can occur as soon as 1 year after the onset of an inflammatory disease or many years later, often proportionate to the degree of inflammation. It is the only type of amyloidosis that occurs in children, such as children with juvenile rheumatoid arthritis.[7] $A\beta_2M$ amyloidosis, a chronic rheumatologic complication that occurs in some patients who undergo long-term dialysis, is related to formation of fibrils of β2-microglobulin in synovial tissues.[8]

The inherited amyloidoses are rare autosomal dominant diseases in which a variant plasma protein forms amyloid deposits beginning in mid life.[9] The most common form is caused by variant transthyretins (TTRs), of which more than 100 types are known to be associated with amyloidosis.[10] One variant, with a substitution of isoleucine for valine

†Deceased.

**TABLE 116-1** Classification of Amyloidosis

| Term | Fibril Composition | Systemic (S) or Localized (L) | Clinical Syndrome |
|---|---|---|---|
| AL | Immunoglobulin light chains (κ or λ) | S, L | Primary; myeloma-associated; systemic or localized in skin, lymph nodes, bladder, tracheobronchial tree |
| AA | Amyloid A protein | S | Secondary; reactive; familial Mediterranean fever |
| $A\beta_2M$ | β2-Microglobulin | S | Long-term hemodialysis or ambulatory peritoneal dialysis |
| ATTR | Transthyretin (one of >100 heritable mutations in ATTRm, or wild-type protein in ATTRwt) | S | ATTRm: familial amyloidotic polyneuropathy and/or cardiomyopathy; ATTRwt: senile systemic or age-related amyloidosis |

at position 122 (V122I), has a carrier frequency that may be 4% in the black population and is associated with late-onset cardiac amyloidosis. Among a large cohort of African-Americans older than age 65 years, the frequency of congestive heart failure and mortality was higher among those carrying the V122I variant of TRR than in age, gender, and ethnically matched control subjects.[11] In an amyloidosis referral population, African-Americans older than age 60 years who presented with amyloid cardiomyopathy were twice as likely to have TTR amyloidosis (ATTR) due to V122I variant of TRR as to have the more common AL type of amyloidosis.[12] Even wild-type TTR can form fibrils in older patients, predominantly involving the heart.[13] Formerly termed "senile systemic amyloidosis," the nomenclature has recently been revised to distinguish the familial form of ATTR in which a mutant allele is inherited (ATTRm) from the age-related form as a result of aggregation of the wild-type protein (ATTRwt).

## PATHOLOGY AND PATHOGENESIS OF AMYLOID FIBRIL FORMATION

### Pathologic Features

Amyloid deposits are widespread in AL amyloidosis and can be present in the extra-cellular spaces and blood vessels of all organs. Deposits in AA amyloidosis usually develop in the kidneys, liver, and spleen, although widespread deposits can be found late in the course of the disease. In $A\beta_2M$ amyloidosis, deposits tend to occur in synovial membrane, cartilage, and bone, but visceral organs are sometimes affected. In ATTR amyloidosis, the nervous system, heart, and thyroid are frequently affected organs, and only small deposits are found elsewhere.

All amyloid deposits stain with Congo red dye and exhibit a unique green birefringence by polarized light microscopy,[14] although the deposits also can be recognized on routine hematoxylin-eosin–stained sections. Electron microscopy shows that amyloid fibrils are 8 to 10 nm wide and of varying lengths, with a 2.5 to 3.5 nm filamentous subunit arranged along the long axis of the fibril in a slow twist.[15] Typing of amyloid deposits can be performed with conventional immunohistochemical staining. False-positive results can occur, however, because of the presence of non-amyloid serum proteins. Immunoelectron microscopy can provide more definitive immunologic identification of the protein in the fibril, or the composition of extracted fibrils can be identified by mass spectrometric proteomic analysis.[16,17]

### Pathogenesis of Amyloid Fibril Formation

The exact mechanism of fibril formation is unknown and may differ among the various types of amyloid.[18] Studies suggest a common underlying mechanism, however, in which a partially unfolded protein intermediate forms multimers and then higher order polymers. Factors that contribute to fibrillogenesis include variant or unstable protein structure, extensive β-conformation of the precursor protein, proteolytic processing of the precursor protein, association with components of the serum or extra-cellular matrix (e.g., serum amyloid P [SAP] component, amyloid enhancing factor, apolipoprotein E, and glycosaminoglycans), and physical properties such as the pH of the tissue site.

AL amyloidosis is a plasma cell dyscrasia with an excess of clonal plasma cells in the bone marrow; it can occur in isolation or in combination with multiple myeloma. Similar cytogenetic changes have been identified in these plasma

cell diseases, suggesting that they may have a common molecular pathogenesis.[19,20] By two-dimensional gel electrophoresis and mass spectrometry, it can be seen that the amyloid fibril deposits are composed of intact 23 kDa monoclonal Ig light chains and C-terminal truncated fragments.[16] Although all κ and λ light chain subtypes have been identified in amyloid fibrils, λ subtypes predominate, and the λ6 subtype seems to have unique structural properties that predispose it to fibril formation,[21] often in the kidney.[22] AL amyloidosis is usually a rapidly progressive disease with amyloid deposits in multiple tissue sites.

The AA type of amyloidosis is a complication of severe, long-standing inflammation, such as that which occurs in chronic inflammatory disorders or infections. AA amyloid fibrils usually are composed of an 8 kDa, 76 amino acid amino-terminal portion of the 12 kDa precursor, serum amyloid A (SAA).[23] SAA is a polymorphic protein encoded by a family of SAA genes, which are acute-phase apoproteins synthesized in the liver and transported by a high-density lipoprotein, HDL3, in the plasma.[24] An underlying inflammatory disease of several years' duration causing an elevated SAA usually precedes fibril formation, although infection can produce AA deposition more quickly. AA fibril formation can be accelerated by an amyloid-enhancing factor present in high concentration in the spleen (which may be early SAA aggregates or deposits), by basement membrane heparan sulfate proteoglycan, or by seeding with AA or heterologous fibrils.[25,26]

Factors related to β2-microglobulin fibril formation are under investigation. The high prevalence of $A\beta_2M$ disease in patients undergoing long-term dialysis provides an argument against an amyloidogenic variant β2-microglobulin molecule. The permeability of dialysis membranes may be a factor because the molecular weight of β2-microglobulin is 11.8 kDa, above the porosity of standard membranes. It has been hypothesized that dialysis membranes may be bioincompatible and may induce pro-inflammatory mediators that stimulate β2-microglobulin and contribute to fibril formation.[27]

In ATTRm and all other forms of familial amyloidosis, inherited mutations or polymorphisms in the genes encoding large serum proteins produce amyloid-prone variants. The process of fibrillogenesis has been best studied for TTR, in which variant TTR molecules are prone to dissociation from stable tetramers, leading to misfolding, polymerization, and fibril formation.[28] The role of aging is intriguing because patients with variant proteins do not have clinically apparent disease until midlife or later, despite the lifelong presence of the abnormal protein.[29] Further evidence of an age-related trigger is that ATTRwt, caused by the deposition of fibrils derived from normal TTR, is exclusively a disease of elderly people.[13]

## DIAGNOSIS

A tissue biopsy specimen showing amyloid fibrils is necessary for the diagnosis of amyloidosis (Figure 116-1). The least invasive biopsy is the abdominal fat aspirate, which is positive in 80% to 90% of patients with AL or ATTR amyloidosis and in 60% to 70% of patients with AA amyloidosis.[30,31] This biopsy is easy to perform after local injection of anesthetic and has a low rate of infectious or hemorrhagic

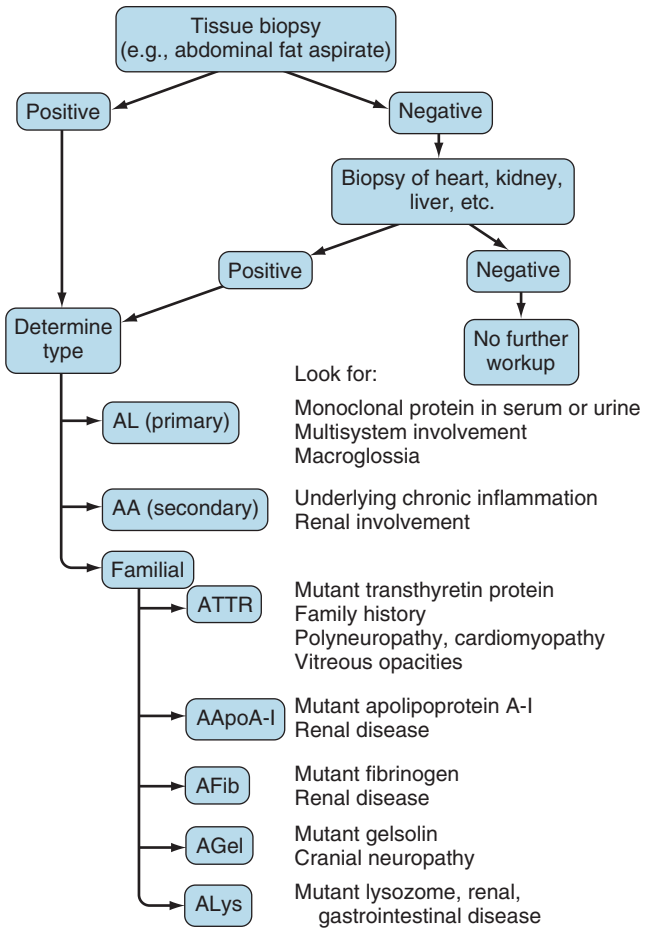

**Figure 116-1** Algorithm for the diagnosis of amyloidosis and determination of type.

complications (Figure 116-2). If the aspirate is negative but clinical suspicion for disease persists, a more invasive tissue biopsy should be performed. Although a biopsy specimen of a clinically involved organ is recommended, almost any tissue biopsy specimen is likely to be positive if the patient has systemic amyloidosis: In a series of 100 patients with AL amyloidosis, 85% of 249 tissue biopsy specimens were positive, including all samples from the kidney, heart, and liver.[32] When the diagnosis of amyloidosis is made, careful evaluation of the entire clinical picture, including the manner of presentation, organ system involvement, underlying disease, and family history, should provide a clue to the type of amyloidosis.

Identification of a plasma cell dyscrasia distinguishes AL from other types of amyloidosis (Figure 116-3). More than 90% of patients have a serum or urine monoclonal immunoglobulin protein or a free light chain on testing by immunofixation electrophoresis or by a recently available nephelometric assay for free light chains.[33,34] In addition, the percentage of plasma cells in the bone marrow is often increased; these are monoclonal on immunohistochemical staining (Figure 116-4).[35] A monoclonal serum protein by itself is not diagnostic of amyloidosis because monoclonal gammopathy of uncertain significance is common in older patients. When monoclonal gammopathy of uncertain significance is present in a patient with biopsy-proven

amyloidosis, however, the AL type is strongly suspected. Immunohistochemical staining by light or electron microscopy should be performed by a laboratory familiar with the techniques and able to perform appropriate controls. Mass spectrometry–based microsequencing of small amounts of protein extracted from fibril deposits ultimately may be the most reliable way to identify the components of the fibrils.[16,17] AA amyloidosis is suspected in patients with renal amyloidosis and a chronic inflammatory condition or infection. AL and ATTR amyloidosis must be ruled out. AA amyloidosis must be confirmed by immunohistochemical staining for AA protein.

Familial amyloidosis must be excluded in every patient who does not have a plasma cell dyscrasia or the AA type of amyloidosis. Although the disease has a dominant inheritance, family history may not be apparent when the disease occurs later in life; in addition, some cases occur through new mutations. Variant TTR proteins usually can be detected by isoelectric focusing (Figure 116-5).[36] With the use of polymerase chain reaction–based sequencing of genomic DNA, mutant TTR alleles, as well as amyloidogenic mutations in genes encoding variant proteins responsible for other types of hereditary amyloidosis, can be detected.[37]

A novel renal amyloid protein, leukocyte chemotactic factor 2, has been found in glomeruli, renal vessels, and interstitium in patients with isolated renal amyloidosis and should be considered in patients who are negative for the more common types of amyloidosis.[38]

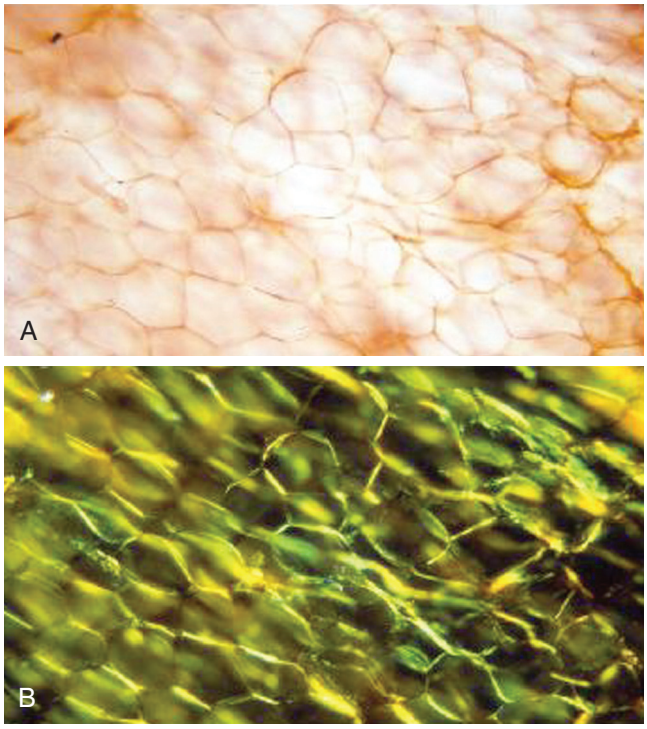

**Figure 116-2** Subcutaneous fat aspirate stained with Congo red viewed by light microscopy **(A)** and polarized light **(B)** (×200). Staining and birefringence are evident in the walls and connective tissues surrounding the adipose cells.

## CLINICAL FEATURES AND TREATMENT

### AL Amyloidosis

AL amyloidosis usually occurs in middle-aged or older people but also can occur in the third or fourth decade of life. It has a wide spectrum of organ system involvement,

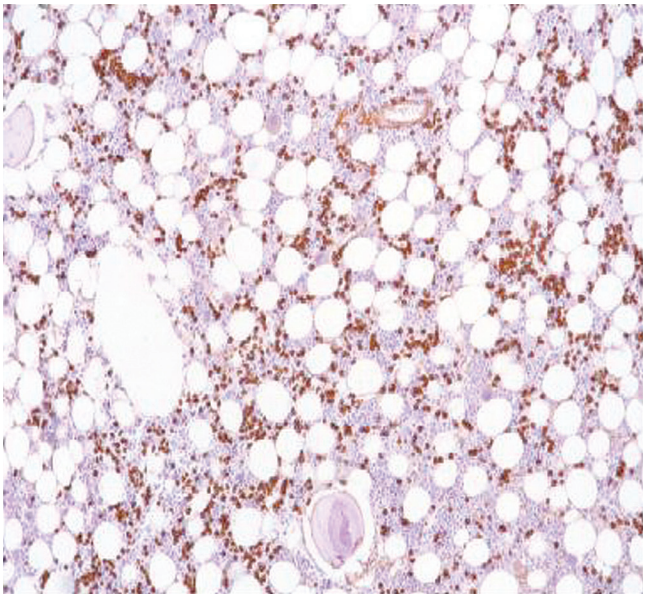

**Figure 116-4** Bone marrow biopsy specimen stained with antibody to λ light chain shows predominance of λ plasma cells and staining of amyloid deposit around a blood vessel (×400).

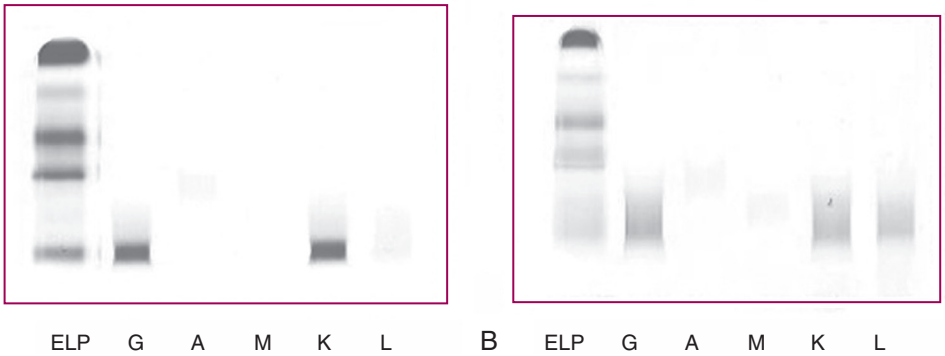

**Figure 116-3** **A,** Pre-treatment serum immunofixation electrophoresis (ELP) shows an IgG (G) κ monoclonal protein. **B,** Post-treatment serum immunofixation ELP shows absence of the monoclonal protein. A, IgA; K, κ chain; L, λ chain; M, IgM.

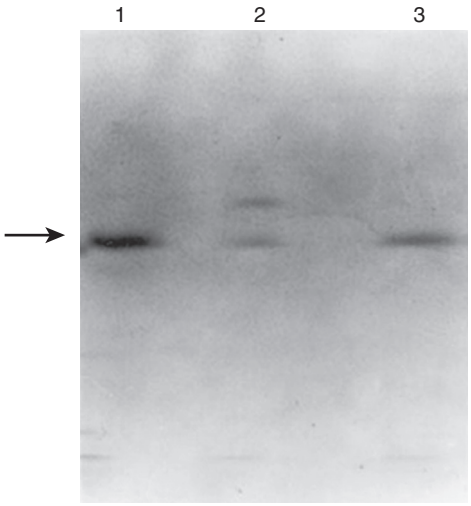

**Figure 116-5** Isoelectric focusing of serum samples shows two bands of variant and wild-type transthyretin (TTR) protein from a patient with TTR amyloidosis *(lane 2)* and a single band of wild-type TTR in normal subjects *(lanes 1 and 3, indicated with an arrow).*

**Figure 116-6** Enlarged tongue of a patient with AL amyloidosis.

and presenting features reflect the organs most prominently affected.[39,40] Initial symptoms of fatigue and weight loss are frequent, but the diagnosis is rarely made until symptoms referable to a specific organ appear.

The kidneys are commonly affected; renal amyloidosis is manifested by proteinuria, sometimes massive, with edema and hypoalbuminemia. Mild renal dysfunction is frequent, but rapidly progressing renal failure is rare. Cardiac involvement, often with congestive heart failure, is a common presentation.[41] An electrocardiogram may show low voltage with a pattern of myocardial infarction. An echocardiogram frequently shows concentrically thickened ventricles and a normal or mildly reduced ejection fraction. Nervous system features include peripheral sensory neuropathy, carpal tunnel syndrome, and autonomic dysfunction with gastrointestinal motility disturbances (early satiety, diarrhea, and constipation) and orthostatic hypotension. Macroglossia, a classic feature pathognomonic of AL amyloidosis, is found in 10% of patients (Figure 116-6). Hepatomegaly may be massive with mild cholestatic abnormalities of liver function, although liver failure is uncommon, even when hepatomegaly is massive. The spleen is frequently involved, and functional hyposplenism may occur, even in the absence of significant splenomegaly. Cutaneous ecchymoses are common, particularly around the eyes, giving the "raccoon-eyes" sign, and appear spontaneously or when provoked by minor trauma (Figure 116-7). Other findings include nail dystrophy (Figure 116-8), alopecia, and amyloid arthropathy with thickening of synovial membranes. The soft tissue and joint manifestations of AL amyloidosis were reviewed in a series of almost 200 patients.[42] Symptoms and signs mimicking rheumatologic diseases, with arthropathy, subcutaneous tissue deposits, muscle pseudohypertrophy, adenopathy, carpal tunnel syndrome, submandibular gland enlargement, and macroglossia, occur in more than 40% of patients with AL amyloidosis.

**Figure 116-7** Periorbital ecchymoses in a patient with AL amyloidosis.

**Figure 116-8** Fingernail dystrophy in a patient with AL amyloidosis.

Timely diagnosis of AL amyloidosis is crucial. Patients with any of these clinical syndromes should be screened for amyloid deposition and for a plasma cell disorder, as previously described. Note that the sensitivity of serum or urine protein electrophoresis without immunofixation is poor; these tests alone are not useful for excluding or diagnosing AL amyloidosis.

Extensive multisystem involvement typifies AL amyloidosis, and median survival with no treatment is usually only about 1 year from diagnosis. Current therapies target clonal bone marrow plasma cells using chemotherapy approaches employed for multiple myeloma (Table 116-2). Oral melphalan and prednisone constituted the first regimen used to treat AL amyloidosis; it was minimally effective[32,43] and is rarely used today because recent studies have shown that substitution of high-dose dexamethasone for prednisone seems to increase response rates significantly.[44]

**TABLE 116-2** Major Treatment Options for Amyloidosis

| |
|---|
| **AL Amyloidosis** |
| Intravenous melphalan with autologous stem cell rescue<br>• Granulocyte colony-stimulating factor–mobilized peripheral blood stem cell collection<br>• Intravenous melphalan, 140-200 mg/m$^2$<br>• Autologous stem cell reinfusion |
| Cyclic oral melphalan and dexamethasone<br>• Melphalan, 0.22 mg/kg/day × 4 days<br>• Dexamethasone, 20-40 mg/day × 4 days, or weekly<br>• Repeat administration every 4 weeks |
| Immunomodulators (including thalidomide, lenalidomide, and pomalidomide, for example)<br>• Oral lenalidomide, 5-15 mg/day × 21 days<br>• Dexamethasone, 20-40 mg weekly<br>• Repeat administration every 4 weeks |
| Proteasome inhibitors (including bortezomib, ixazomib, and carfilzomib, for example)<br>• Intravenous bortezomib, 1.6 mg/m$^2$ weekly × 4<br>• Dexamethasone, 20-40 mg weekly × 4<br>• Repeat every 5 weeks |
| **AA Amyloidosis** |
| Aggressive treatment of underlying inflammatory disease<br>Medical or surgical treatment of underlying infection<br>Colchicine, 1.2-1.8 mg/day for AA amyloidosis secondary to familial Mediterranean fever<br>Antifibril drug, eprodisate (investigational) |
| **ATTR Amyloidosis** |
| Orthotopic liver transplantation<br>Transthyretin stabilizers: diflunisal and tafamidis<br>RNA-based therapeutics: siRNA and antisense RNA (investigational) |

High-dose intravenous (IV) melphalan followed by autologous stem cell transplantation is highly effective. Of more than 500 patients treated with such protocols at Boston Medical Center, approximately 40% of evaluable patients had achieved a hematologic complete response when assessed 1 year after treatment; most patients experienced significant improvement or stabilization of organ function.[45] Median survival in treated patients exceeds 4.5 years and is durable.[46] Other referral centers have found similar results.[47-49] However, patients with amyloidosis and organ impairment have high rates of treatment-related morbidity and mortality with aggressive treatment. Factors that contribute to mortality include amyloid cardiomyopathy, poor performance or nutritional status, reduced pulmonary function, and amyloid-associated bleeding disorders. The only randomized multicenter study comparing oral melphalan chemotherapy with IV melphalan chemotherapy with stem cell support was plagued by high treatment-related mortality and failed to show benefit for the high-dose regimen.[50] At centers with experience in treating this disease, this treatment is still considered first line in low-risk patients. Age alone[51] or renal failure[52] does not exclude patients from such treatment. Cardiac biomarkers have been used to stratify risk for high-dose therapy.[53]

For patients with significantly impaired cardiac function or arrhythmias resulting from amyloid involvement of the myocardium, median survival is only about 6 months without treatment, and stem cell mobilization and high-dose chemotherapy are associated with great morbidity. In such patients, orthotopic cardiac transplantation followed by intravenous melphalan and stem cell rescue to prevent fibrillogenesis in the transplanted heart or other organs can be effective.[54]

New agents that are efficacious in reducing the plasma cell burden in multiple myeloma are being tested for AL amyloidosis. These agents include immunomodulators such as lenalidomide, a derivative of thalidomide[55-57] that affects the bone marrow microenvironment, as well as proteasome inhibitors to which plasma cells are particularly sensitive, such as bortezomib.[58-60] These agents generally have been tested for use in patients for whom alkylator chemotherapy has failed; current clinical trials are examining these novel agents in combination with alkylators, as induction before transplant, and for maintenance. Weekly rather than biweekly dosing of bortezomib appears to reduce the incidence of peripheral neuropathy and may be safer in patients with AL amyloidosis. Innovative approaches target the amyloid fibrils themselves or accessory binding proteins. The anthracycline derivative 4′-iodo-4′-deoxydoxorubicin was noted to cause resorption of amyloid deposits in model systems, but clinical trials have failed to show any clinical benefit.[61] The agent R-1-[6-[R-2-carboxy-pyrrolidin-1-yl]-6-oxo-hexanoyl]-pyrrolidine-2-carboxylic acid binds serum amyloid P protein and accelerates clearance from the circulation and from amyloid fibrils in animal models.[62] The addition of an antibody against SAP appears to further accelerate clearance.[63] Thus far, trials using this approach have not shown a clear clinical benefit. Antibodies directed against the amyloidogenic proteins themselves are also in pre-clinical and clinical development as potentially useful agents for imaging and therapy. A humanized monoclonal antibody, NEOD001, which specifically targets the amyloid that accumulates in AL amyloidosis, is in early stage clinical trials (Prothena Corporation, Dublin, Ireland).

Supportive treatment is recommended for patients with all types of amyloidosis (Table 116-3). At times, supportive treatment may be lifesaving (e.g., heart or kidney transplantation, renal dialysis, cardiac pacemaker, and nutritional support). Digitalis, calcium channel blockers, and β-blockers are relatively contraindicated because toxicity has been observed at therapeutic levels.

## AA Amyloidosis

AA amyloidosis can occur at any age. The primary clinical manifestation is proteinuria, renal insufficiency, or both.[5] A study from Finland found AA amyloidosis to be the most common cause of nephrotic syndrome in patients with rheumatoid arthritis.[64] Hepatomegaly, splenomegaly, and autonomic neuropathy frequently occur as the disease progresses; cardiomyopathy occurs rarely. With chronic inflammatory diseases, amyloid progression is slow, and survival is often longer than 10 years, particularly with treatment for end-stage renal disease. In contrast, untreated infections, such as osteomyelitis, tuberculosis, or leprosy, can produce a more rapidly progressive amyloid syndrome, which remits with effective medical or surgical treatment of the infection.

The major therapy in AA amyloidosis is treatment of the underlying inflammatory or infectious disease. Treatment that suppresses or eliminates the inflammation or infection also decreases the SAA protein. For familial Mediterranean fever, colchicine, 1.2 to 1.8 mg/day, is the appropriate treatment. Colchicine has not been helpful for AA amyloidosis

**TABLE 116-3** Supportive Treatment for All Types of Amyloidosis

| Organ System | Symptom | Treatment Options |
|---|---|---|
| Cardiac | Congestive failure | Salt restriction of 1-2 g/day<br>Diuretics: furosemide, spironolactone, and metolazone |
| | Arrhythmia | Pacemaker<br>Automatic implantable cardiac defibrillator<br>Antiarrhythmics |
| Renal | Nephrotic syndrome | Salt restriction of 1-2 g/day<br>Elastic stockings and leg elevation<br>Maintaining dietary protein<br>Angiotensin-converting enzyme inhibitor, if blood pressure tolerates it |
| | Renal failure | Dialysis (long-term ambulatory peritoneal dialysis or hemodialysis) |
| Autonomic nervous | Orthostatic hypotension | Midodrine<br>Increased dietary salt or added fludrocortisone, depending on edema<br>Elastic stockings |
| | Gastric atony or ileus | Small frequent feedings (6/day), low in fat<br>Oral nutritional supplements<br>Jejunostomy tube feeding<br>Parenteral nutrition |
| Gastrointestinal | Diarrhea | Low-fat diet (≤40 g)<br>Psyllium hydrophilic mucilloid (Metamucil)<br>Loperamide hydrochloride (Imodium)<br>Tincture of opium<br>Parenteral nutrition |
| | Macroglossia | Soft solid diet<br>Partial glossectomy (rarely effective) |
| Peripheral nervous | Sensory neuropathy | Avoid trauma<br>Gabapentin (Neurontin), 100-300 mg 3 times daily<br>Amitriptyline, 25-50 mg at bedtime<br>Pregabalin (Lyrica), 50-100 mg 3 times daily |
| | Motor neuropathy | Ankle-foot orthotics for foot drop<br>Physical therapy |
| Hematologic | Intracutaneous bleeding<br>Factor X deficiency | Avoid trauma, anti-platelet agents<br>Factor replacement (recombinant factor VIIa and prothrombin complex concentrates)<br>Splenectomy for splenomegaly |

of other causes or for other amyloidoses. A multicenter randomized trial using a new antiamyloid drug, eprodisate, has been completed; the drug was found to significantly delay worsening of renal function in patients with AA amyloidosis.[65] A second multicenter trial requested by the Food and Drug Administration is now under way. Eprodisate interferes with the interaction of AA amyloid protein and glycosaminoglycans in tissues and prevents fibril formation and deposition.

## $A\beta_2M$ Amyloidosis

Several distinct rheumatologic conditions are observed in people with $A\beta_2M$ amyloidosis, including carpal tunnel syndrome, persistent joint effusions, spondyloarthropathy, and cystic bone lesions. Carpal tunnel syndrome is usually the first symptom of disease. Persistent joint effusions accompanied by mild discomfort occur in 50% of patients who undergo dialysis for longer than 12 years. Involvement is bilateral, and large joints (shoulders, knees, wrists, and hips) are more frequently affected. The synovial fluid is non-inflammatory, and β2-microglobulin amyloid deposits can be found if the sediment is examined with Congo red staining. Spondyloarthropathy with destructive changes in the intervertebral disks and paravertebral erosions have occurred in association with β2-microglobulin amyloid deposits. Cystic bone lesions sometimes leading to pathologic fractures have been described in the femoral head, acetabulum, humerus, tibial plateau, vertebral bodies, and carpal bones. Although less common, visceral β2-microglobulin amyloid deposits occasionally occur in the gastrointestinal tract, heart, tendons, and subcutaneous tissues of the buttocks.

Treatment for $A\beta_2M$ amyloidosis is difficult to provide because the 11 kDa β2-microglobulin molecule is too large to pass through a dialysis membrane. Consistent with a postulated role of copper in initiating $A\beta_2M$ fibrillogenesis,[66] copper-free dialysis membranes seem to reduce the incidence of disease. Patients undergoing continuous ambulatory peritoneal dialysis usually have lower plasma levels of β2-microglobulin than do patients undergoing hemodialysis and may not develop amyloid deposits as quickly. Symptoms of arthropathy are common, and prevalence may approach 100% of people undergoing dialysis for longer than 15 years. Patients who have received kidney transplants after developing $A\beta_2M$ report improvement in symptoms.

## ATTR Amyloidosis

The clinical features of ATTR and AL in patients presenting with involvement of heart and peripheral nerves overlap, such that the diseases cannot be reliably distinguished by clinical presentation alone. A family history makes ATTRm more likely, but many patients with ATTRm

seem to present sporadically with new mutations in the germline. Within each family, disease begins at nearly the same age, and symptoms usually include neuropathy, cardiomyopathy, or both. Peripheral neuropathy begins as a lower extremity sensory and motor neuropathy and progresses to the upper extremities. Autonomic neuropathy is manifested by gastrointestinal symptoms of diarrhea with weight loss and orthostatic hypotension. Cardiomyopathy and conduction system defects are similar to those caused by AL, although in people with ATTR amyloidosis, heart failure is less common, and the prognosis is better.[67] Vitreous opacities caused by amyloid deposits are pathognomonic of ATTRm.

The TTR variant, V122I, is a common allele in African-Americans and is associated with cardiomyopathy. In a large referral population, 25% of African-American patients with amyloidosis had this TTR variant.[11,12] ATTRm due to V122I is likely underdiagnosed because of lack of physician awareness and the difficulty of distinguishing amyloid and hypertensive cardiomyopathy without an endomyocardial biopsy.

Without intervention, survival after ATTR disease onset is 5 to 15 years. Orthotopic liver transplantation, which removes the major source of variant TTR production and replaces it with normal TTR, is the major treatment for ATTR amyloidosis.[68,69] Liver transplantation arrests disease progression, and some improvement in autonomic and peripheral neuropathy may occur.[70] Cardiomyopathy does not improve and in some patients seems to worsen after liver transplantation.[71] A beneficial long-term outcome depends on transplantation early in the disease course.[72]

Two international multicenter randomized placebo-controlled clinical trials have been conducted to test the efficacy of the NSAID diflunisal, a salicylic acid derivative, and an analog, tafamidis, for the treatment of ATTRm polyneuropathy, based on laboratory studies showing that these agents stabilize the normal circulating TTR tetramer, preventing dissociation into monomers, misfolding, and aggregation.[73] Diflunisal, which was tested in patients with a variety of TTR mutations for 2 years, met its primary endpoints, resulting in a reduction in the rate of progression of neurologic impairment and preserving quality of life.[74] Tafamidis, tested only in patients with V30M ATTRm for a shorter time, also showed some benefit.[75] These drugs are now being tested for efficacy in people with ATTR cardiomyopathy, including that caused by the wild-type protein. ATTRm is also the first disease being investigated with small interfering RNA therapeutics in studies sponsored by Alnylam Pharmaceuticals, Inc., Cambridge, Mass., as well as with antisense oligonucleotides developed by Ionis Pharmaceuticals, Inc., Carlsbad, Calif. In the future, patients may be treated with a combination of agents designed to downregulate TTR protein expression in the liver and to stabilize the residual TTR protein in the circulation.

## CONCLUSION

Timely and accurate diagnosis of amyloidosis is essential because effective treatments for some forms of amyloidosis are available or are undergoing clinical trials. The first step is recognition of a clinical syndrome consistent with amyloidosis, followed by an appropriate biopsy or fat aspirate to identify tissue fibrils. The next priority should be to determine whether an associated plasma cell disorder can be identified, because AL is the most rapidly progressive type of systemic amyloidosis, and therapy should be initiated before heart, kidney, or liver failure occurs. Definitive identification of the amyloid precursor protein is essential for appropriate therapy, and amyloid referral centers can provide specialized diagnostic techniques and access to clinical trials. An understanding of the biophysical properties of amyloid proteins and of the mechanisms of protein misfolding and tissue damage will enable the further development of more specific and less toxic antiamyloid therapeutics.

CHAPTER 117

# Sarcoidosis

Nadera J. Sweiss • Peter Korsten • Robert P. Baughman

**KEY POINTS**

- Sarcoidosis is a heterogeneous multisystem inflammatory disease of unknown cause characterized by the development and accumulation of noncaseating granulomata in any organ system.
- Sarcoidosis occurs worldwide and affects people of all racial and ethnic backgrounds, but prevalence and severity are increased in African-American patients.
- The pathogenesis of sarcoidosis involves the interplay of different cells, cytokines, and other inflammatory mediators in a susceptible host.
- Rheumatologic manifestations are common in sarcoidosis but are often overlooked or misdiagnosed.
- No treatments have been approved by the U.S. Food and Drug Administration for extrapulmonary manifestations, including sarcoid arthritis.
- Current treatment options include first-line treatment with glucocorticoids, second-line treatment with disease-modifying antisarcoid drugs like methotrexate, and third-line treatment with TNF inhibitors, which may be used depending on the severity and the type of organ system involved.

Sarcoidosis is an orphan, systemic, and clinically heterogeneous disorder. Its cause has yet to be identified, but environmental, genetic, and infectious causes have been suggested. The hallmark of sarcoidosis is the development and accumulation of noncaseating granulomas in any organ system. Organ system involvement, which is unpredictable and varies between patients, is the major determinant of morbidity and mortality in sarcoidosis. Any organ system can be involved, but the lungs are affected in more than 90% of cases. Lymphatic, skin, and ocular findings are also common. Given the variability of sarcoidosis manifestations, diagnosing this disorder is often difficult. Patients may be asymptomatic or present with a range of nonspecific symptoms, or specific symptoms such as cough, dyspnea, burning of eyes, or a rash may suggest the diagnosis.[1] When extrapulmonary symptoms develop, they sometimes result in rheumatologic manifestations including but not limited to arthritis, skin lesions, arthralgias, and neuropathy.[2] Rheumatologists often are consulted when the presentation is atypical or when multiple organs are affected.

## CLASSIFICATION CRITERIA

No classification criteria for sarcoidosis have been adopted by the American College of Rheumatology or the European League Against Rheumatism for sarcoidosis. However, the American Thoracic Society, the European Respiratory Society, and the World Association of Sarcoidosis and Other Granulomatous Disorders suggest a diagnosis of sarcoidosis if the following criteria are fulfilled: (1) a compatible clinical picture, (2) histologic demonstration of noncaseating granulomas, and (3) exclusion of other diseases capable of producing a similar clinical picture.[1]

## EPIDEMIOLOGY

Sarcoidosis is a global disease. Because of its clinical heterogeneity and variable diagnostic criteria in different countries, the worldwide prevalence and incidence of sarcoidosis have been difficult to calculate. In Northern Europe, up to 40 cases per 100,000 people have been reported,[3,4] whereas in a study from Eastern Europe, only 3.68 cases of sarcoidosis per 100,000 people were found.[5] The incidence of sarcoidosis in Japan is also low, with one study estimating it to be 3.7 cases per 100,000 individuals.[6] Within countries, incidence rates may vary between races. In the United States, the annual incidence of sarcoidosis is more than three times higher in black people (35.5 per 100,000) than in white people (10.9 per 100,000).[7] Furthermore, the disease course of sarcoidosis is more progressive and mortality may be higher in African-Americans.[8,9] Despite numerous epidemiologic studies of sarcoidosis, many clinicians and researchers believe that estimates of prevalence and incidence are lower than actual rates of the disease because of inaccurate diagnoses or asymptomatic cases that are never diagnosed.[10]

Although sarcoidosis affects men and women of all ages and from diverse ethnic backgrounds,[4,11] some disparities in how it affects these groups have been noted. The fact that it affects slightly more women than men has been confirmed in studies from around the world; estimates indicate that 57% of patients with sarcoidosis are women.[4] Relative to men, women with sarcoidosis have a greater number of ocular and neurologic manifestations. People of any age may acquire the disease, but the median age of onset is around 40 years.[4] A second peak of incidence has been reported at around age 65 years, especially in women.[8,12]

## ETIOLOGY

The exact cause of sarcoidosis remains elusive despite years of research; however, multiple etiologic factors have been identified. The heterogeneity of the disease suggests that multiple causative agents may be responsible for the

Supplemental images available on the accompanying ExpertConsult website.

variable disease manifestations of sarcoidosis. Given the immunopathogenic mechanisms that underlie sarcoidosis, such a disease trigger might be a T cell antigen that stimulates the cascade of events leading to granuloma formation. Because the lungs are affected in more than 90% of sarcoidosis cases, it is likely that an environmental agent (including an infectious agent, potentially exposed via the pulmonary route) might contribute to the onset of sarcoidosis.

Both inorganic and organic environmental factors with antigenic capabilities have been implicated in the pathogenesis of sarcoidosis. Early studies on the causes of sarcoidosis suggested a link between sarcoidosis and agents associated with a rural lifestyle, such as the lumber industry and burning wood.[13,14] In a case-control etiologic study of sarcoidosis (ACCESS), it was found that burning of agricultural debris and wood is particularly associated with pulmonary sarcoidosis but not with systemic sarcoidosis.[15] In a different analysis of the ACCESS trial, radiation, insecticides, mildew, and mold were environmental factors associated with the systemic sarcoidosis phenotype.[16] More recently, a sarcoidosis-like phenotype has been reported in fire department rescue workers involved in the World Trade Center catastrophe.[17] These findings may indicate that each of these unique sarcoidosis subtypes has its own causes.

Because of clinical and histologic similarities, numerous methods have been used to look for an infectious agent as a cause of sarcoidosis, with most studies focusing on *Mycobacterium tuberculosis* or *Propionibacterium acnes*. When in situ hybridization was used, *Mycobacterium tuberculosis* catalase-peroxidase protein (mKatG) was found in nearly 40% of tissue samples from patients with sarcoidosis. Recombinant mKatG protein was then used to measure mKatG antibodies in patients with sarcoidosis, which were present in 50% of patients studied.[18] Other investigators have found evidence of an immunologic reaction to additional mycobacterial antigens such as ESAT-6.[19,20] *P. acnes* has been found more frequently in granulomas from patients with sarcoidosis but also can be found in people without sarcoidosis, and thus its primary role in pathogenesis remains unclear.[21-23] These studies suggest that sarcoidosis may represent overexposure of the patient to a commonly encountered microorganism associated with hyperreactive resultant immune responses. Because several types of bacteria have been associated with sarcoidosis, some clinicians have attempted to use antibiotics or antimycobacterial agents to manage the disease. Although skin sarcoidosis has on occasion responded to these treatments,[24,25] their usefulness in treating other forms of sarcoidosis appears to be minimal.[21] In addition, serum amyloid A (SAA) accumulates in granulomas as a result of the hyperimmune T helper (Th)1 cell response response necessary for killing the infecting agent.[26] This mechanism could be an explanation for the ongoing chronic granulomatous inflammation seen in many patients with sarcoidosis.[27] Furthermore, blood levels of SAA correlate with the disease stage and thus could serve as a biomarker and/or therapeutic target.[28]

## GENETICS

Compelling studies of familial clustering and the incidence of sarcoidosis among different racial groups indicate that sarcoidosis susceptibility is influenced by the interplay of genetic factors. In the ACCESS study, first-degree relatives were reported to have a fivefold increased risk of developing the disease.[17] Associations have been found between risk of sarcoidosis and class I and II human leukocyte antigen (HLA) gene products, which have essential roles in antigen presentation. It is considered likely that a susceptibility locus for sarcoidosis exists within the HLA gene region, as is the case with other autoimmune diseases and cancers such as Hodgkin's lymphoma. An intriguing analysis of data from the ACCESS study identified associations between genetic factors (HLA alleles), environmental factors, and sarcoidosis phenotypes. In considering together several of the factors postulated to cause sarcoidosis, a compelling argument can be made for a genetic factor that predisposes individuals to the disease and a subsequent environmental exposure that triggers the onset of sarcoidosis. Specifically, Rossman and colleagues found that HLA-DRB1*1101 and insecticide exposure at work are significantly associated with cardiac sarcoidosis and hypercalcemia.[29] A similar relationship between HLA-DRB1*1101, mold and musty odors, and pulmonary sarcoidosis was described.[29]

Certain HLA alleles have been found to be protective or associated with increased susceptibility or different disease phenotypes. In Caucasian populations, HLA-DRB1*01 and HLA-DRB1*04 were protective against the disease, whereas HLA-DRB1*03, *11, *12, *14, and *15 were risk factors for sarcoidosis.[30] Interestingly, HLA-DRB1*11 was found to be related to presentation of the mycobacterial antigens ESAT-6 and mKatG (previously described), thus providing a possible mechanistic link between a genetic background and reaction to a pathogen.[31]

Moreover, HLA-DRB1*03 was associated with spontaneous resolution, whereas HLA-DRB1*14 and HLA-DRB1*15 were associated with a chronic course of the disease.[32] In European patients with Löfgren's syndrome, which is an acute form of sarcoidosis characterized by bilateral hilar lymphadenopathy (BHL), fever, and erythema nodosum and/or periarticular ankle inflammation, HLA-DRB1*03 is four times more common than in healthy individuals[33] and has been associated with favorable prognostic factors. In one study, most DRB1*03$^+$ patients experienced resolution of Löfgren's syndrome within 2 years after diagnosis. By contrast, nearly half of patients without this allele had chronic disease.[34] The mechanism underlying this difference in disease course remains unknown. A relationship between HLA-DRB1*03 and interferon (IFN)-γ homozygosity has been suggested in sarcoidosis. Wysoczanska and colleagues reported that when combined, these two genetic factors increase the risk of Löfgren's syndrome, which may be indicative of a complex gene-gene interaction underlying this sarcoidosis phenotype.[35]

Genetic studies of non-HLA genes have been inconclusive.[30] The two candidate genes that have been most consistently associated with sarcoidosis are TNF and the IL-23 receptor (IL-23G) gene. Other possible candidate genes have produced conflicting results. The TNF G-308A polymorphism was found to be predictive of response to treatment with TNF inhibitors,[36] which might help tailor treatment based on pharmacogenetics in the near future.

Analysis of gene-expression profiles to distinguish between tuberculosis and sarcoidosis has revealed similarities

between the two diseases; however, matrix metallopeptidase 14 could be identified as most distinctive marker for sarcoidosis.[46] Ongoing genome-wide association studies are seeking to identify additional genes that may be linked to sarcoidosis onset and susceptibility. To date, these studies have identified several novel gene candidates. In particular, *BTNL2*, *ANXA11*, *RAB23*, *OS9*, *CCDC88B*, *PRDX5*, and *NOTCH4* have been identified as potential loci for sarcoidosis susceptibility.[30] Most of these genes play a role in the immune system, but their functional role has yet to be characterized.

More recently, epigenetic changes (such as DNA methylation) that influence gene expression without changing the primary nucleotide sequence have been identified as an important mechanism in many diseases, such as cancer and kidney disease, but also in autoimmune diseases.[38] In sarcoidosis, methylation changes of telomeres and specific microRNAs (such as miR-144, miR-20a, miR-302c, miR-92b, and miR-206) have been found. Their functional role and the clinical consequences remain to be elucidated.[39]

Taken together, it is likely that sarcoidosis might be further subclassified depending on the genetic backgrounds and their respective immunologic responses,[32] thus enabling us to identify individual therapeutic targets.

## PATHOGENESIS

Granuloma formation is a hallmark of sarcoidosis disease. The underlying immunologic events include (1) exposure to one or more (unknown) antigens, (2) activation of antigen-presenting cells (macrophages and/or dendritic cells), (3) a T cell response in an effort to eliminate the antigen, and (4) granuloma formation.

Physiologically, granulomas act as shields, protecting tissues from pathogens and thereby pre-empting inflammatory reactions. Granulomas consist of a core of mononuclear phagocytes, such as epithelioid cells, multinucleated giant cells, and macrophages, which are encased by lymphocytes, including B cells, $CD4^+$ T cells, and $CD8^+$ T cells.[12] The immunologic reaction is influenced by a genetic background that renders individuals more or less susceptible to the development of a "sarcoidosis phenotype" (described in the subsequent text).

Granuloma formation occurs in different stages, divided into the initiation, accumulation, and effector phases and resolution.[40] After antigen exposure, macrophages detect antigens via pattern recognition receptors (e.g., Toll-like receptors [TLRs]) and then internalize and process these antigens. In sarcoidosis, it is mainly TLR2 and TLR4 that are involved.[41] They then present these antigen(s) to the T cell receptor via HLA molecules. This step requires the presence of co-stimulatory molecules (such as CD80, CD83, and CD86) to determinate the immune response (activation or inhibition). One of these inhibitory signals may be mediated by the *butyrophilin-like 2 (BTNL2)* gene. Locally activated naïve $CD4^+$ Th cells differentiate into activated $CD4^+$ Th1-like cells during the accumulation phase, causing subsequent elevations in Th1-associated inflammatory mediators, such as IL-2, IFN-$\alpha$, IFN-$\gamma$, monocyte chemotactic protein-1, macrophage inflammatory protein-1, and granulocyte-macrophage colony-stimulating factor. $CD4^+$ Th cells also interact with antigen-presenting cells to initiate the development of granulomas and to preserve granulomas.[3] Thus T cells undergo oligoclonal proliferation in areas of immune system activity. At this point in the disease process, lymphocyte levels are typically increased at the sites of inflammation, but peripheral blood lymphopenia may occur as a result of sequestration. The ratio of CD4/CD8 cells becomes elevated in the lungs and other affected organs. During the effector phase, T cells and macrophages release mediators (IL-12, IL-15, IL-18, and TNF), which amplifies the Th1-driven inflammatory response.

Macrophage-derived cytokines contribute to the external signaling milieu that favors the differentiation of $CD4^+$ cells to Th1 cells.[42,43] Ultimately, a feedback loop from a downstream-produced cytokine cascade induces macrophages to differentiate into epithelioid cells, which gain secretory capability, lose phagocytic capacity, and fuse to form multinucleated giant cells.[3] These epithelioid cells form the cellular basis of granulomas. Also contributing to granuloma formation are Th2 cells. These cells synthesize fibronectin and C-C motif ligand 18 (CCL18). During resolution, release of these mediators results in a positive feedback loop of CCL18-activated and macrophage-mediated collagen formation. Although granulomas spontaneously resolve without causing damage in most cases, this cycle leads to fibrosis in up to 25% of patients with sarcoidosis.[3] As patients' fibrosis becomes more extensive, their prognosis worsens. Although the mechanisms responsible for granuloma fibrosis have not been fully characterized, patterns of cytokines change (upregulation of transforming growth factor [TGF]-$\beta$), and Th2 cells may lead to an increased ratio of CD8 to CD4 cells. Fewer than 5% of patients die of sarcoidosis, but fibrosis leading to respiratory failure is a contributing factor in many sarcoidosis-related deaths. In recent years, additional cell populations such as regulatory T cells (Tregs) and Th17 cells that release IL-17A (see Chapter 12) have been found to be upregulated in individuals with sarcoidosis.[44-46] Interestingly, nicotine treatment improves TLR responsiveness and normalizes the numbers of Tregs in individuals with sarcoidosis,[47] supporting the anecdotal observation that the incidence of sarcoidosis is diminished in smokers.[48]

Overall, there appear to be two possible immunologic scenarios in sarcoidosis: an intense immune reaction in patients with active disease, finally resulting in antigen clearance, or chronic disease with less inflammation but the inability to eradicate the inciting agent and subsequent chronic stimulation of the immune response, resulting in organ damage such as lung fibrosis.[41]

## CLINICAL FEATURES

Sarcoidosis can affect every organ system, with the lungs the most commonly affected organ. Joint symptoms are quite common in sarcoidosis, affecting up to 25% of patients.[2] The eyes (uveitis and retinal vasculitis), liver (abnormal liver function tests), lymph nodes (enlargement), and skin (lupus pernio, papules, nodules, plaques, and scar sarcoidosis [tattoos]) are the most frequent extrapulmonary organs affected (see Table 117-1).[32] However, rheumatologists are more likely to be confronted with patients who have systemic, atypical, or primarily musculoskeletal manifestations or disease that is refractory to

**TABLE 117-1** Extrapulmonary Localizations of Sarcoidosis

| | Prevalence | Symptoms | Investigations |
|---|---|---|---|
| Skin | ~15% | Papules, nodules, plaques, scar sarcoidosis (tattoos), lupus pernio, subcutaneous sarcoidosis, erythema nodosum | Biopsy (except for lupus pernio and erythema nodosum*) |
| Lymph nodes | 10%-20% | Mostly cervical or supraclavicular; inguinal, axillary, epitrochlear, submandibular sites also possible; painless and mobile | Biopsy |
| Eye | 10%-30% | Anterior, intermediate or posterior uveitis, retinal vasculitis, conjunctival nodes, lacrimal gland enlargement | Systematic ophthalmology examination, slit-lamp examination, fluorescein angiography |
| Liver | 20%-30% | Often symptom-free, abnormal liver function tests in 20%-30%, hepatomegaly, rarely hepatic insufficiency, chronic intrahepatic cholestasis, portal hypertension | Liver function tests, abdominal ultrasound or CT, rarely biopsy if moderate or severe abnormalities on liver tests or if the diagnosis is uncertain |
| Spleen | ~10% | Splenomegaly, rarely pain or pancytopenia, very rarely splenic rupture | Ultrasound and CT |
| Heart | 2%-5% | Atrioventricular or bundle branch block, ventricular tachycardia or fibrillation, congestive heart failure, pericarditis, impairment of sympathetic nerve activity, sudden cardiac death | Electrocardiography, echocardiography, 24-h Holter monitoring, MRI, perfusion scintigraphy, 18F-FDG-PET; biopsies are rarely performed because of low yield |
| Nervous system | ~5% | Facial nerve palsy, optic neuritis, leptomeningitis, diabetes insipidus, hypopituitarism, seizures, cognitive dysfunction, deficits, hydrocephalus, psychiatric manifestations, spinal cord disease, polyneuropathy, small-fiber neuropathy | CSF investigation, MRI, intraepidermal nerve fiber density, SFN screening list |
| Joints† | 15%-25% | Acute or chronic arthritis, in acute arthritis often bilateral ankle swelling with periarthritis/tenosynovitis, rarely dactylitis; chronic arthritis oligo- or polyarticular, most often associated with systemic disease; Jaccoud deformity, trabecular changes, phalangeal cysts, or granulomatous erosions possible | Plain radiographs, ultrasound, MRI |
| Kidney | 0.5%-2% | Rare symptoms, acute kidney injury, chronic renal insufficiency, hypercalcemia, hypercalciuria, nephrocalcinosis, kidney stones, granulomatous interstitial nephritis | 24-h urinary calcium, creatinine, proteinuria (spot urine), kidney biopsy, ultrasound |
| Parotitis | 4% | Symmetrical parotid swelling, Heerfordt's syndrome when associated with uveitis, fever, and facial nerve palsy | |
| Nose | 0.5%-6% | Nasal stuffiness, nasal bleeding, crusting, anosmia | Sinus CT, rhinoscopy, biopsy |
| Larynx | 0.5%-1% | Hoarseness, breathlessness, stridor, dysphagia | Laryngoscopy, biopsy |
| Skeletal muscles | 1%-2% | Proximal muscle weakness, amyotrophy, myalgia, intramuscular nodes | Creatine phosphokinase test, MRI, 18F-FDG-PET, electromyography, biopsy |
| Genitourinary tract | | All organs can be involved, including uterus, epididymis, and testicle | Biopsy; imaging as appropriate |
| Gastrointestinal tract | 1% | Most often symptom-free; esophagus, stomach, small intestine, and colon can be involved | Endoscopy, biopsy |

*Biopsies of erythema nodosum do not demonstrate granulomas.

standard treatment. Additional symptoms are sarcoidosis-associated fatigue (present in about 50% to 70% of patients),[49] small-fiber neuropathy (44%), which is difficult to diagnose and treat,[50] and cognitive dysfunction.[51] Musculoskeletal involvement can present as osseous sarcoidosis (axial manifestation or sacroiliitis) in up to 13% of patients[52] or sarcoid myopathy in up to 75%, the latter of which is only rarely symptomatic.[2] Between 15% and 25% of patients with sarcoidosis have arthritis, which is the most frequently observed rheumatologic symptom of sarcoidosis. In patients with sarcoidosis, arthritis can be acute or chronic; the acute form is most common. Chronic arthritis is typically associated with multisystem sarcoidosis.[53]

## Acute Sarcoid Arthritis

Febrile arthropathy is the most frequently observed joint involvement in sarcoidosis. Although any joint may be involved, the condition usually is symmetric, involving ankles, knees, wrists, and elbows, and exists with BHL and erythema nodosum. Of note, ankle swelling is most often due to periarthritis or tenosynovitis rather than true synovitis when assessed by ultrasound or MRI.[53a,53b] Patients with acute sarcoid arthritis experience pain and stiffness, and their joints may be swollen or tender (see supplemental Figure 117-1 on ExpertConsult.com). Acute sarcoid arthritis sometimes resolves within weeks of onset, but occasionally

symptoms last for several months. Once this condition resolves, it usually does not recur.

In a study of patients with acute sarcoid arthritis, Visser and colleagues[53] prospectively evaluated patients and published criteria to assist in diagnosis. Of 579 participants, 55 patients (9%) eventually were diagnosed with sarcoid arthritis. Diagnoses were made after it was established that patients had a combination of arthritis and BHL, as determined by chest radiography. From the findings of their study, investigators established criteria with 93% sensitivity and 99% specificity to guide physicians in differentiating between sarcoid and other causes of arthritis (Table 117-2).

In addition to Visser's criteria, most symptoms of sarcoid arthritis vary among patients. Patients with sarcoid arthritis frequently have elevated erythrocyte sedimentation rates,[53,54] but other symptoms, such as fever, are observed only in up to 66% of patients.[53-56] Of note, in a small number of patients with acute sarcoid arthritis, abnormal alterations may develop in the bones that can be seen on radiographs of the hands or feet. In some patients, sarcoid dactylitis may be the presenting symptom (see Figure 117-1C and E), characterized by swollen soft tissues surrounding affected fingers, erythematous skin, or tenderness. Individuals with dactylitis also may have nail abnormalities, such as dystrophy. Therefore, it is important to rule out other conditions that affect the nails, such as psoriatic arthritis, when making sarcoid arthritis diagnoses.

Other skeletal areas that may be affected by sarcoidosis include nasal bones, pelvic girdle structures, ribs, and the skull. Patients with lupus pernio may be particularly at risk for the development of abnormalities in their nasal bones. Because of similarities between a patient with sarcoidosis who has nasal bone involvement and a patient who has granulomatosis with polyangiitis (GPA), it is important to distinguish between these conditions.[57] Serology may be useful because most patients with GPA will have a positive anti-neutrophil cytoplasm antibody (ANCA), but sarcoidosis does not lead to a positive ANCA.[58] On the other hand, about 60% of patients with sarcoidosis will have an elevated angiotensin-converting enzyme (ACE) level at presentation, which is not seen in the presence of vasculitis.[57] Lesions in the pelvic bones (see Figure 117-1D) or in the spine (see Figure 117-1F) may at first lead one to suspect

**TABLE 117-2** Visser's Criteria for Sarcoidosis in Patients with Arthritis and Bihilar Lymphadenopathy

| Of the following criteria, patients must have three of four characteristics to establish the diagnosis (sensitivity 93%, specificity 99%): |

cancer metastases. Therefore, a comprehensive assessment is warranted in patients who present with changes in their skeletal bones, even if they exhibit other symptoms typical of sarcoidosis.

## Chronic Sarcoid Arthritis

The chronic form of sarcoid arthritis is less common than the acute form, and in the United States it affects more African-American than white people. It most often affects people with systemic sarcoidosis and multiorgan involvement and typically manifests as oligoarthritis or polyarthritis. Sarcoid arthritis can have a varied presentation. Joint destruction (granulomatous erosions) or Jaccoud's deformity (i.e., deformity without obvious destruction) can occur when inflammation persists, and phalangeal cysts or a trabecular pattern can be present on plain radiographs.

In some patients, joint symptoms manifest early in the course of sarcoidosis, whereas other patients experience sarcoid arthritis several years after onset of the disorder. Lupus pernio and chronic uveitis may manifest concomitantly with the chronic form of arthritis.

As is the case with other organ system manifestations, several conditions may mimic sarcoid arthritis and should be excluded. For example, symmetric oligoarthritis or polyarthritis and an elevated rheumatoid factor are common features of sarcoid arthritis, but they may also result from reactive arthritis or rheumatoid arthritis (RA). Furthermore, a subset of patients with RA may experience some lung dysfunction, which can cause confusion in differentiating RA from sarcoidosis. In addition, it has been reported that coincident sarcoidosis eventually develops in some patients with RA, although it is rare for sarcoidosis to coexist with connective disease disorders. Therefore, it is crucial for physicians to distinguish between the two conditions or to determine whether the two diseases are comorbid within the same patient.[59]

In patients with migratory polyarthritis, rheumatic fever may be suspected, particularly when joint symptoms manifest before additional sarcoidosis-related symptoms are noted. A biopsy of the synovium or tendon sheaths may be helpful, with characteristic granulomas appearing upon pathologic examination. Differential diagnoses for patients with monarthritis include gout, septic arthritis, and calcium pyrophosphate dihydrate–positive arthritis (see Tables 117-3, 117-4, and supportive content for detailed consideration of the diagnostic approach).[2]

## DIAGNOSIS AND DIAGNOSTIC TESTS

The diagnosis of musculoskeletal disease related to sarcoidosis must be examined on the basis of two different presentations. The first is a patient with known sarcoidosis who presents with musculoskeletal symptoms. The other is a patient with musculoskeletal disease in whom sarcoidosis is a possibility. Although the evaluations may be similar, a patient with known sarcoidosis elsewhere who has musculoskeletal manifestations consistent with sarcoidosis is usually assumed to have sarcoidosis in that area. However, in a patient with musculoskeletal involvement and no known sarcoidosis elsewhere, a biopsy usually will be required to confirm the diagnosis. The biopsy specimen may be from the lung or skin, but in some cases it will be from muscle.

**TABLE 117-3** Evaluation of a Patient with Sarcoidosis

Modified from American Thoracic Society: Statement on sarcoidosis: joint statement of the American Thoracic Society (ATS), the European Respiratory Society (ERS) and the World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) adopted by the ATS Board of Directors and by the ERS Executive Committee, February 1999. *Am J Respir Crit Care Med* 160:736–755, 1999.

Sarcoidosis is a diagnosis of exclusion. In clinical practice, other conditions often are suspected first when considering only clinical symptoms (e.g., Hodgkin's lymphoma or tuberculosis with pulmonary findings and/or systemic symptoms). The main goal of the workup is therefore to gather enough clinical clues and compatible features to diagnose sarcoidosis with sufficient certainty and to exclude other diagnoses that warrant a totally different treatment approach. Figure 117-1 presents some features consistent with the disease.[60] In many instances, the diagnosis will rely heavily on the finding of granulomas in a tissue biopsy. However, many other conditions can lead to a granulomatous reaction, as summarized in Table 117-5. Although sarcoidosis granulomas tend to be noncaseating and nonnecrotizing, a significant number of patients with sarcoidosis exhibit evidence of some necrosis in part of their granulomatous response. A biopsy is usually not required for some presentations such as Löfgren's syndrome, Heerfordt's syndrome (defined as fever, uveitis, parotitis, and cranial nerve palsy), BHL with uveitis, and asymptomatic BHL.[61]

The heterogeneity of the disease leads to varied clinical presentations, which may result in delayed diagnosis. In one study of 189 patients with sarcoidosis, it was found that only 15.3% of patients received a diagnosis during their first visit to a physician.[60] Moreover, sarcoidosis can affect any organ, which may cause a patient to be referred to a specialist who may not commonly manage sarcoidosis.[60] Patients with pulmonary symptoms are often misdiagnosed as having asthma. For individuals with musculoskeletal manifestations, the presentation of sarcoidosis may be similar to that of other conditions, most notably autoimmune disorders.[62]

For the patient who presents with musculoskeletal disease and possible sarcoidosis, a vigilant approach is mandatory.

**TABLE 117-4** Comparison of the Features of Sarcoidosis and Other Rheumatologic Diseases

| | Sarcoidosis | SLE | RA | PsA | Systemic Vasculitis |
|---|---|---|---|---|---|
| Clinical findings | Lungs, eyes, and skin most common; any other organ (e.g., heart, brain, skin, bone, and liver) also may be affected | Joints, kidneys (nephritis), mucous membranes, circulatory system, nervous system, lymph nodes, spleen | Joints (most common), lungs, blood vessels | Joints (oligoarthritis, polyarthritis), skin (psoriatic lesions), nails (dystrophy, dactylitis) | Blood vessels (wall thickening), skin (purpura, infarct ulcers), nervous system (headache, meningitis, seizures), joints (arthritis), kidneys (hypertension), heart, GI system |
| Radiographic findings | Bilateral and mediastinal hilar adenopathy, reticulonodular opacities | Bilateral, diffuse air space opacity; diaphragm elevation ("shrinking lung syndrome") | Joint space narrowing, joint erosions, inflammation | Joint space narrowing, erosions, ossification near joints | Granulomatous lesions; multiple bilateral nodules; patchy areas of consolidation |
| Pathologic findings | Noncaseating granulomas | Inflammation, blood vessel abnormalities such as vasculitis, immune complex deposits | Swollen synovium; presence of fibroblast-like and macrophage-like synoviocytes, macrophages, T and B cells | Increased synovial vascularity, dilated blood vessels, neutrophil infiltration | ANCA staining pattern on neutrophils and monocytes; patchy infiltrates, vessel wall granulomas, fibrous tissue |
| Laboratory findings | Elevated ACE; hypercalcemia; presence of ANAs, ANCAs, and anti-dsDNA | Anti-dsDNA, anti-Smith, ANAs, RNP, antithrombin, anti-Ro/SS-A, anti-La/SS-B, anti-topoisomerase, aPL | Rheumatoid factor, ACPA, aPL | ANA (common), anti-dsDNA, rheumatoid factor, anti-Ro, anti-RNP (rare), aPL | ANCA, aPL, inflammatory markers (CRP) |

| | MCTD | Scleroderma | Anti-phospholipid syndrome | Sjögren's syndrome | Ankylosing spondylitis | Reactive arthritis |
|---|---|---|---|---|---|---|
| Clinical findings | Raynaud's phenomenon; joints, muscles, lungs, heart, kidneys, and nervous system may be affected | Skin (tightening, thickening, induration), joints, GI system, lung, heart, kidney | Blood vessels (arterial/venous thrombosis, thrombocytopenia, fetal loss) | Eyes, mouth, and mucous membrane dryness; joints (arthritis), skin, kidneys, nervous system, and lymph nodes may be affected | Vertebral arthritis, back pain, stiffness, synovitis, peripheral arthritis, pulmonary symptoms, iritis | Arthritis, conjunctivitis, urethritis; usually following a genitourinary or GI infection |
| Radiographic findings | Diffuse periarticular osteopenia; swelling of soft tissue; joint erosions, joint space narrowing, tuft resorption, and soft tissue atrophy | Pulmonary fibrosis, diffuse reticulonodular pattern | Patchy infiltrates | Mild joint space narrowing | Vertebral inflammation; sacroiliitis; bone erosions, syndesmophytes | Proliferation at tendon insertion; sacroiliitis; syndesmophytes |
| Pathologic findings | Autoantigen modifications, B and T cell activation | Excess matrix deposition, fibrosis; endothelial cell dysfunction and death; destruction of small vessels | Structural glomerular changes | B cell infiltration | Capsular fibrosis; ossification | Bacterial infection *(Shigella, Salmonella, Campylobacter)* |
| Laboratory findings | ANA, RNP, aPL | ANA (anti-topoisomerase), aPL, ACAs | Lupus anticoagulant, aPL, anti–protein C, anti-prothrombin, anti–protein S, anti-annexin | ANA, anti-Ro/SS-A, rheumatoid factor, aPL | Elevated ESR, leukocytosis, HLA-B27 | ANCA, HLA-B27; elevated ESR, CRP |

ACA, Anti-cardiolipin antibody; ACE, angiotensin-converting enzyme; ACPA, anti-citrullinated protein antibody; ANA, anti-nuclear antibody; ANCA, anti-neutrophil cytoplasm antibody; aPL, anti-phospholipid antibody; CRP, C-reactive protein; dsDNA, double-stranded DNA; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; HLA, human leukocyte antigen; MCTD, mixed connective tissue disease; PsA, prostate-specific antigen; RA, rheumatoid arthritis; RNP, ribonucleotide protein; SLE, systemic lupus erythematosus.

| Laboratory data | Elevated angiotensin-converting enzyme<br>Elevated serum calcium<br>Elevated alkaline phosphatase<br>Elevated soluble IL-2 receptor | Positive anti-neutrophil cytoplasm antibody |

A comprehensive multisystem evaluation, as is commonly performed in rheumatology practice, should prove informative. For example, hilar adenopathy on a posterior chest roentgenogram is seen in about two-thirds of patients. Scadding proposed a staging system of the chest roentgenogram[63]: stage 1 disease consists of hilar adenopathy alone (see Figure 117-1A); stage 2 disease is hilar adenopathy plus infiltrates; stage 3 is infiltrates alone; and stage 4 is fibrosis. Although this scoring is commonly used, differences may be noted in staging of the roentgenogram, even among sarcoidosis experts.[64] Patients may have evidence of disease on a chest computed tomography (CT) scan. Table 117-6 lists some of the features that, when present, support or refute the diagnosis.[65] These features include erythema nodosum, lupus pernio (see Figure 117-1B), cranial seventh nerve paralysis, and hypercalcemia.

For patients with sarcoidosis, several tests (summarized in Table 117-3) have been proposed to serve as a minimal evaluation.[66] These tests reflect the fact that sarcoidosis is a multiple-organ disease and that one needs to look for evidence of specific organ involvement. Because serum ACE levels may or may not be elevated in patients with sarcoidosis and therefore are not accurate for the diagnosis,[67] other biomarkers for the diagnosis (chitotrisodase[68]) or activity (soluble IL-2 receptor [sIL-2R], neopterin, chitotriosidase, lysozyme, KL-6, and amyloid A[32]) are being evaluated. sIL-2R and neopterin correlate with 18F-fluorodeoxyglucose-positron emission tomography (18F-FDG-PET) uptake,[69] but its use in clinical practice has not been finally determined. Because no biomarkers with sufficient sensitivity or specificity have been identified for sarcoid arthritis, we suggest regular evaluation with routine clinical examination (observing for signs of inflammation, swelling, or radiographic changes) and standard inflammatory markers (erythrocyte sedimentation rate and C-reactive protein) to assess for severity/progression in arthritis.

MRI with administration of gadolinium may identify involvement of sarcoidosis in the brain[70] or the heart.[71] MRI findings also may be useful in identifying bone sarcoidosis or sarcoid arthritis and may identify asymptomatic lesions.[71a]

Several lines of evidence have indicated that 18F-FDG-PET may be useful for diagnosis and assessment in (extra) pulmonary sarcoidosis,[72] but it usually is not recommended as a first diagnostic tool. 18F-FDG-PET can be used to determine which organs are affected, particularly when no evidence of lung involvement is found; this includes cardiac sarcoidosis.[71] Furthermore, 18F-FDG-PET can point investigators to appropriate organs to biopsy when no distinct organ system involvement is obvious.[73] For pulmonary sarcoidosis, endobronchial ultrasound is used to help the bronchoscopist select appropriate biopsy sites for transbronchial needle aspiration.[74]

Criteria for specific organ involvement in patients with known sarcoidosis have been proposed and updated.[75,76] Definitive organ involvement may be obvious or can be established by positive results of a granuloma biopsy from the affected tissue. For example, it is possible that arthritis with no other cause may be attributed to underlying

sarcoidosis. However, patients with phalangeal cystic changes almost definitely can consider their arthritis to be a manifestation of their sarcoidosis[75] (Table 117-4).

Highly probable sarcoid arthritis includes the typical features of the trabecular pattern, osteolysis, cyst formation, and punched-out lesions. Signs of sarcoidosis that is at least probable include dactylitis, nodular tenosynovitis, and positive findings of PET, MRI, or gallium-67 bone imaging. Arthralgias are a sign of possible sarcoid arthritis, and patients who present with nonspecific arthritis are categorized under "no consensus." This classification has limitations and has not been validated in a prospective clinical setting.[76]

# TREATMENT

## General Approach

Prednisone and adrenocorticotropic hormone have both been approved for treatment of pulmonary sarcoidosis, but no treatment for extrapulmonary sarcoidosis, including sarcoid arthritis, has been approved by the U.S. Food and Drug Administration (FDA). With the advent of 18F-FDG-PET scanning and other imaging modalities, it is likely that a larger proportion of patients with asymptomatic but widespread disease will be diagnosed. Decisions to begin immunosuppressive therapy, however, depend on symptoms (e.g., persistent cough or dyspnea) and organ dysfunction (e.g., abnormal pulmonary function tests) and not on the mere number of organs affected (sometimes termed "systemic sarcoidosis"). As a general rule, current treatment options are divided into first-, second-, and third-line therapies.[77] First-line therapy for most manifestations (with the exceptions of sarcoidosis-associated fatigue and small-fiber neuropathy) are corticosteroids. A dose of 20 to 40 mg per day should be maintained for 1 to 3 months and then tapered to a maintenance dose of 5 to 10 mg/day, which, empirically, is usually maintained for 1 year.[78] Second-line therapies include so-called "disease-modifying antisarcoid drugs" (DMASDs), including methotrexate, azathioprine, leflunomide, hydroxychloroquine, chloroquine, mycophenolate, and cyclosporine. For refractory cases, TNF inhibitors can be used as third-line therapy. The two best studied agents of this class of drugs are infliximab and adalimumab. INF has been studied in two placebo-controlled trials and improved FVC and dyspnea, especially in patients with longer disease duration and more dyspnea at baseline.[78a,78b] ADA has shown some effectiveness in pulmonary sarcoidosis.[79] Etanercept has proven to be ineffective for pulmonary and ocular sarcoidosis.[80,81] In a recent trial, the TNF inhibitor golimumab and ustekinumab, an antibody against IL-12/IL-23, were found to be ineffective in the treatment of pulmonary sarcoidosis.[82] B cell inhibition by rituximab had mixed results in individuals with refractory sarcoidosis in a small clinical trial,[83] but it has been effective in singular cases.[84] A definite recommendation cannot be made for using rituximab to treat sarcoidosis.

In addition, it must be remembered that paradoxical reactions to biologic agents can occur, including positivity for anti-nuclear antibody, drug-induced lupus erythematosus, demyelinating disorders, and sarcoid-like granulomatosis.[85,86] A sarcoid-like reaction also has been reported with ustekinumab,[87] suggesting that other mechanisms than upregulation of interferon-α through TNF inhibition[88] might play a role. A genetic predisposition (possibly TNF polymorphisms) is likely, but at present, it is impossible to predict which patients will experience this reaction. Therefore, a high index of suspicion is mandatory when using this type of drug. Tables 117-7 and 117-8 provide an overview of treatment recommendations for the various disease manifestations.

## Management of Sarcoid Arthritis

No randomized trials have been conducted that can guide clinical decision making. To help guide clinicians in management, we have proposed a treatment algorithm, which is shown in Figure 117-2.[2] NSAIDs, methotrexate, and local or low-dose systemic corticosteroids are our preferred first-line therapies. Alternatively, hydroxychloroquine and other DMASDs may be used. Using information obtained from the diagnostic evaluation, the clinician usually makes treatment decisions after carefully considering the disease severity and its probable clinical course, as revealed by its radiographic progression.

The proposed algorithm requires regular patient visits to monitor disease activity and therapeutic efficacy and tolerability. Responders continue to take first-line agents until disease resolution or, alternatively, treatment failure. Before nonresponders are prescribed second-line therapies, higher doses of corticosteroids may be used, depending on tolerability and manifestations of toxicity. For patients who require second-line medications, two options are available: (1) methotrexate may be administered to methotrexate-naïve patients, or (2) nonmethotrexate disease-modifying antisarcoid drugs (e.g., hydroxychloroquine, and azathioprine) as monotherapy or combinations thereof may be prescribed to patients who have an inadequate response to first-line methotrexate.

For patients for whom this treatment approach fails, one can consider an alternative third-line biologic therapy or an aggressive course of systemic corticosteroids with careful monitoring of toxicity. Alternatively, participating in a clinical trial may be appropriate for some patients.

Vitamin D metabolism represents a more complex issue in sarcoidosis than in other rheumatic diseases.[89] Patients with sarcoidosis might be more sensitive to calcium and vitamin D substitution,[90] with the associated risks of hypercalcemia and hypercalciuria, which are present in up to 10% of patients who don't receive vitamin D supplements. The mechanism usually attributed to hypercalcemia has been increased production of 1,25-dihydroxyvitamin D (1,25-$OH_2D$) by epithelioid cells in the granuloma (1α-hydroxylase activity). This risk must be balanced against the adverse effects of potential chronic vitamin D deficiency, and patients often require treatment for osteoporosis because of long-term glucocorticoid use. Bisphosphonates alone may be adequate to treat corticosteroid-induced osteoporosis.[91] Patients who do not receive glucocorticoid therapy do not seem to have a lower bone mineral density per se because of sarcoidosis.[92] Recently, higher levels of 25-hydroxyvitamin D (25-OHD) were associated with a higher frequency of fractures in patients with sarcoidosis.[93] The authors found that levels between 10 and 20 ng/mL were associated with

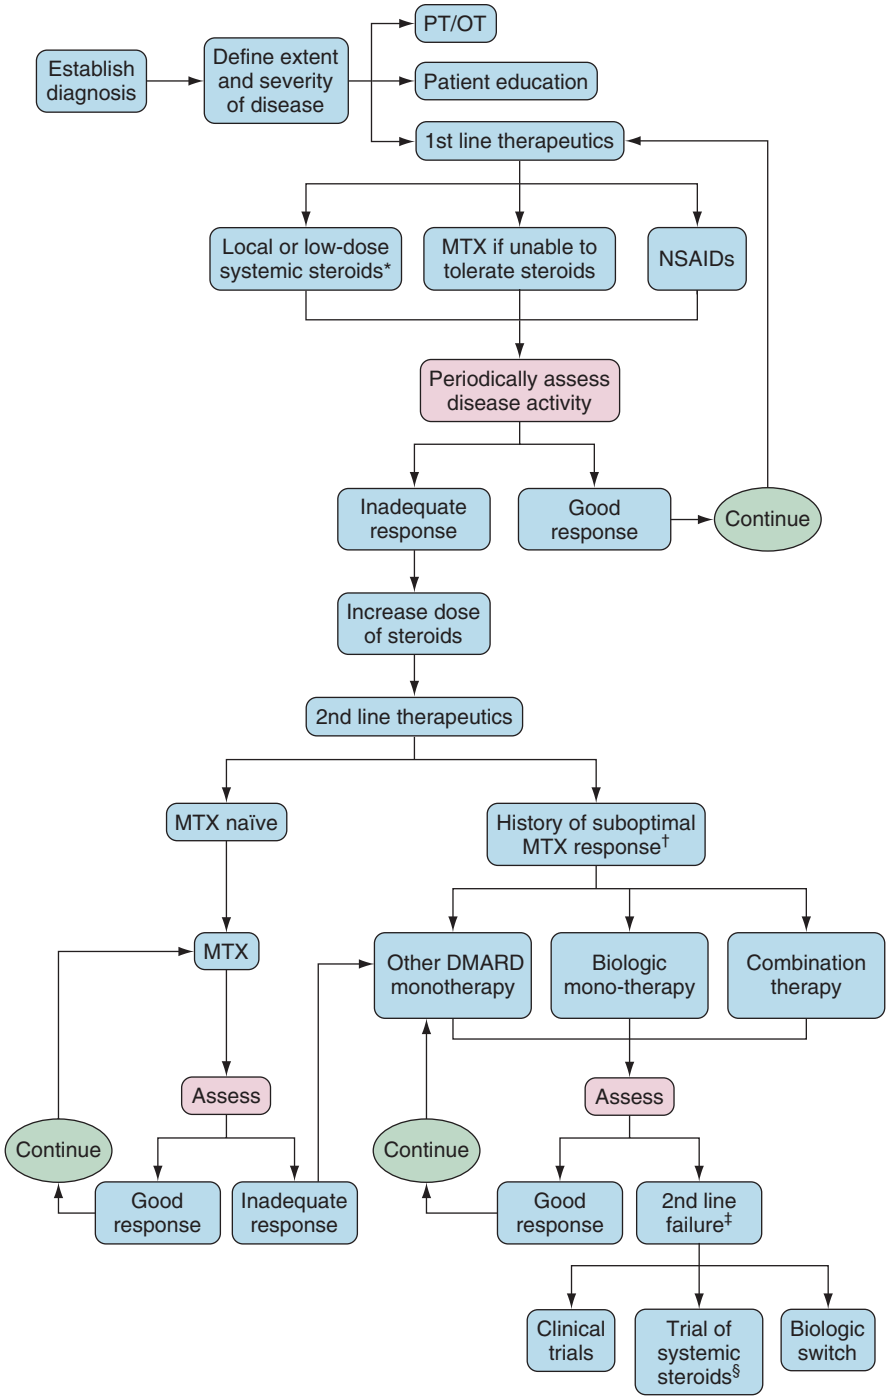

**Figure 117-2** Algorithm describing an approach to treating sarcoidosis arthritis. *Low-dose steroids: <10 mg prednisone daily. †Suboptimal response to methotrexate (MTX): intolerance to drug, lack of satisfactory efficacy with dosage up to 25 mg/wk, or a contraindication to medication use. ‡Disease-modifying anti-rheumatic drug (DMARD) failure: progressive disease or drug intolerance. §Methylprednisone preferred over prednisone if prednisone has been used previously. the lowest risk for fractures. Because of the disassociation between 25-OHD and 1,25-$OH_2$D in sarcoidosis, it seems reasonable to measure both levels to ascertain which patients should receive vitamin D supplements.[89,94,95]

## OUTCOME AND PROGNOSIS

The overall mortality in sarcoidosis is low (about 5%),[96] and many patients with spontaneous regression will never require treatment. In people who need treatment, important differences exist between African-American and white patients. African-American patients with sarcoidosis are known to experience a more severe and systemic disease; mortality is 12 times higher in this population.[97]

## CONCLUSION

Much remains to be learned about sarcoidosis. The causes of this disease remain unclear, and no medications have been approved by the FDA for its treatment with the exception of prednisone and ACTH gel, which was approved in the 1950s on the basis of a few case reports. Clinical trials are currently ongoing to evaluate the safety and efficacy of Acthar gel in various sarcoidosis phenotypes. Although increasing attention has been directed to the underlying mechanisms of granuloma formation and the cause (including an infectious cause), full details of sarcoidosis immunopathogenesis have yet to be determined. Appropriate animal models and candidate genes are needed to help advance our understanding of this disease. Large clinical trials are warranted.

We have presented an algorithm that can be used in treating patients with an established diagnosis of sarcoidosis. However, treatment approaches vary by institution and by individual clinicians as a result of a myriad of conflicting studies that have been published about sarcoidosis management. The diversity of clinical presentations and the lack of large, well-designed, randomized, controlled clinical trials addressing the various clinical phenotypes currently make it impossible to provide more specific treatment recommendations. Furthermore, therapeutic choices will likely differ according to the type and extent of organ system involvement observed in individual patients. It is probable that symptoms such as sarcoidosis-associated fatigue or small-fiber neuropathy are underrecognized because patients must be specifically assessed for their presence. The systemic nature of this disease coupled with the complexity of phenotypic presentation among various ethnic groups and within the same patient makes it difficult to study this complex disease.

For relapsed and refractory disease, steroid-sparing agents including cytotoxic drugs and novel biologic therapies such as TNF inhibitors and B cell depleting therapy increasingly have been used. TNF inhibitors have been investigated in numerous sarcoidosis studies because of the potential role of TNF and other pro-inflammatory factors in sarcoidosis pathogenesis. Limiting their usefulness in this setting are mounting reports of granulomatous reactions to TNF blocking therapies in patients treated with these agents for nonsarcoidosis indications. In other words, TNF inhibitors may help treat *and may cause* sarcoidosis.[98-101] With this point in mind, it is relevant to our discussion

**TABLE 117-8** Overview of Drugs Used to Treat Sarcoidosis

| Drug | Dose Recommendation | Required Monitoring | Comments |
|---|---|---|---|
| Corticosteroids | 20-40 mg/day initial<br>Taper to 5-10 mg/day<br>Lower doses may be considered | Physical examination<br>BP<br>Blood glucose | |
| Methotrexate | 5-25 mg/wk | CBC<br>LFT<br>Kidney function | Lower doses usually sufficient<br>Risk of hypersensitivity pneumonitis 5% in people with RA; in people with sarcoidosis, possibly lower |
| Azathioprine | 1-2 mg/kg/day | CBC<br>LFT | Consider TPMT testing before treatment<br>Concomitant use of allopurinol with a high risk of toxicity |
| Leflunomide | 10-20 mg/day | CBC<br>LFT | Lung toxicity reported<br>Silent liver fibrosis |
| Hydroxychloroquine | 200-400 mg/day (max 5 mg/kg/day) | Ophthalmologic examination once a year (may be extended to every 5 years) | |
| Mycophenolate mofetil | 500-3000 mg/day | CBC<br>LFT | |
| Cyclophosphamide | 500-1000 mg IV or 500 mg/m$^2$ IV every 3-4 wk | CBC, especially after 10-14 days<br>Hematuria<br>Kidney function | Rarely used<br>Typically 6-8 cycles are used |
| Infliximab | 3-5 mg/kg IV at weeks 0, 2, and 6, then every 4-8 wk | CBC<br>Liver and kidney function test<br>Infections | Test for tuberculosis/hepatitis before treatment<br>Heart failure<br>Concomitant use with another drug (MTX) recommended to prevent antibody formation |
| Adalimumab | 40 mg SC every 1-2 wk | Infections<br>CBC<br>Liver and kidney function test | Test for tuberculosis/hepatitis before treatment<br>Possibly higher dose preferred<br>Heart failure |
| Rituximab | 1 g IV on day 0 and 14 | Serum immunoglobulins every 3-6 mo | Progressive multifocal leukoencephalopathy is a rare complication<br>Test for hepatitis before treatment |
| Thalidomide | 50-200 mg/day | CBC | Birth defects<br>Polyneuropathy relatively common |
| ACTH analogue | 40-80 units IM or SC | Blood pressure<br>Electrolytes | Adrenal suppression with rapid withdrawal<br>Cushing's syndrome with prolonged use<br>GI ulcers/bleeding |

ACTH, Adrenocorticotropic hormone; BP, blood pressure; CBC, complete blood cell count; GI, gastrointestinal; IM, intramuscular; IV, intravenous; LFT, liver function test; MTX, methotrexate; RA, rheumatoid arthritis; SC, subcutaneous; TPMT, thiopurine S-methyltransferase.

that the presentation of TNF inhibitor–induced sarcoidosis, similar to all phenotypes of sarcoidosis, is a unique entity, but it does overlap with that of other autoimmune diseases. Furthermore, TNF inhibitors have been reported to induce autoimmune diseases other than sarcoidosis, including systemic lupus erythematosus, vasculitis, interstitial lung disease, and demyelinating disorders. Diagnosing these conditions in patients with TNF inhibitor–induced sequelae is critical.

Collaborative multicenter studies utilizing a translational personalized approach are required to best serve patients with sarcoidosis, ensure safety, and prevent long-term toxicity while improving quality of life.

CHAPTER 118

# Hemochromatosis

Gaye Cunnane

**KEY POINTS**

- Elevated ferritin levels (>200 µg/L) and transferrin saturation (>45%) in the absence of other causes are useful screening measures for hereditary hemochromatosis (HHC).
- Genetic testing should be reserved for patients with suggestive biochemical abnormalities, a positive family history of HHC, or both.
- Disease phenotype varies greatly among individuals with similar HHC genotypes including genes encoding *HFE,* hepcidin, hemojuvelin transferrin receptor 2, and ferroportin.
- Diet, alcohol intake, and other risk factors for chronic liver disease all influence the clinical expression of HHC.
- Phlebotomy is an effective treatment for decreasing iron stores.
- Some clinical manifestations of disease improve with treatment (e.g., constitutional symptoms, diabetes mellitus, and liver enzyme abnormalities), whereas others are not affected (e.g., arthritis, hypogonadism, and cirrhosis).
- Atypical osteoarthritis or chondrocalcinosis should trigger a search for an underlying metabolic disorder.
- Early diagnosis and treatment improve outcome.

Hemochromatosis refers to the presence of excess iron in body tissues because of increased iron absorption. Primary or hereditary hemochromatosis (HHC) is an autosomal recessive disease, whereas secondary hemochromatosis refers to iron overload as a result of increased iron availability, ineffective erythropoiesis, or inherited abnormalities of iron metabolism.

Hemochromatosis was first recognized in the 1880s in a series of case reports that described "bronze diabetes" and "pigmented cirrhosis," but von Recklinghausen[1] is credited with the first use of the term in 1889. In 1935, the familial pattern of HHC was described by Sheldon,[2] who suggested that the disease was due to an inborn error of metabolism. In 1955, Finch and Finch[3] showed that HHC was caused by abnormal iron absorption in the presence of a normal diet. At that time, premorbid recognition of the problem was uncommon, and most cases were diagnosed at autopsy. In 1972, serum ferritin became available as a measure of iron stores. Three years later, Simon and colleagues[4] discovered that the HHC gene was present on chromosome 6, close to the human leukocyte antigen (HLA)-A locus. It took 21 more years for the mutated gene, *HFE*, to be described, and in the past decade, it has been recognized that other gene mutations also can cause iron overload.[5] Genetic testing has revolutionized the diagnosis of HHC, although the phenotype of any given mutation may vary greatly.[6,7] Nevertheless, the detection of such genes has greatly enhanced the overall prognosis of this condition by allowing the disease to be diagnosed at a pre-clinical stage in high-risk individuals. This discovery, along with improved knowledge at a molecular level, has further aided our understanding of the pathogenesis and treatment of HHC and helped many patients achieve a normal life expectancy.

## IRON METABOLISM IN HEALTH AND DISEASE

Iron has an essential role in erythropoiesis and in normal cellular function. Along with anemia, chronic iron deficiency results in a variety of other clinical manifestations such as changes to the nails, tongue, esophagus, and muscles.[8] In normal adults, the average total body iron content is 3 to 4 g, mostly contained within hemoglobin, but also present in myoglobin and cytochromes, in addition to the storage proteins, ferritin and hemosiderin (Table 118-1). Of a typical daily Western diet of 10 to 20 mg of iron, 1 to 2 mg is absorbed by duodenal enterocytes each day.[9,10] Heme dietary sources from fish and meat have a higher bioavailability than nonheme sources, such as vegetables. The addition of ascorbic acid to the meal increases absorption of nonheme iron, whereas tannins, bran, and phytates inhibit iron absorption.[11,12]

Iron homeostasis, which is tightly controlled at cellular and molecular levels, is influenced by regulatory feedback between body iron requirements and intestinal iron absorption.[13] Dietary iron enters the body in the duodenum, where, in the ferrous state, it gains access to the enterocyte via divalent metal transporter 1. It is then either stored intracellularly and eventually excreted through the feces or absorbed via ferroportin transfer out of the enterocyte, aided by ferroxidase activity of the ceruloplasmin homologue, hephaestin.[14] Circulating iron is then either used (mainly by erythroid cells) or stored (in the liver or macrophages).

Communication between sites of iron uptake, utilization, and storage is tightly controlled. Ferroportin facilitates release of intra-cellular iron and is a major player in iron homeostasis, modulated by hepcidin, which plays a central role in the process.[13,15] Hepcidin is produced by the liver in response to changes in iron status and negatively regulates iron levels.[16] It acts directly on ferroportin by binding to it and causing it to be internalized by the cell and destroyed.[17] A signaling pathway for bone morphogenetic protein (BMP)-6 regulates hepcidin by binding to a specific receptor

**TABLE 118-1** Mechanisms of Iron Metabolism

| Term | Role in Iron Metabolism |
|---|---|
| Ferritin | Major iron storage protein in iron storage diseases and inflammation<br>Markedly increased in adult-onset Still's disease<br>Plasma levels reflect iron stores (e.g., 1 ng/mL ferritin = 10 mg iron) |
| Transferrin | Transporter protein for iron in plasma<br>Synthesized in liver<br>Increased in iron deficiency states |
| Transferrin saturation | Serum iron (μg/dL) ÷ total iron-binding capacity (μg/dL) × 100 in iron deficiency anemia/chronic disease/ferroportin mutation in hemochromatosis/ineffective erythropoiesis/iron overload states/severe liver failure |
| Iron regulatory proteins | Maintain iron homeostasis by modulating synthesis of transferrin receptors/ferritin/duodenal iron transporter |
| HFE protein | Identified in cells of deep crypts of duodenum and in Kupffer cells<br>Thought to modulate uptake of transferrin-bound iron into duodenal crypt cells<br>May regulate iron absorption via interaction with hepatocytes expressing hepcidin transferrin receptor 2 or JFV genes |
| Iron exporter proteins | Ferroportin/hephaestin/divalent metal transporter 1 |
| Hepcidin | Acute phase reactant produced by liver<br>Intrinsic anti-microbial activity<br>Negative regulator of iron absorption<br>Reduces iron release from macrophages<br>Prevents iron loss by reducing entry of iron into bloodstream via inhibition of ferroportin<br>Mutations found in some families with juvenile hereditary hemochromatosis |
| Hemojuvelin (HJV) | Expressed in liver, heart, and skeletal muscle<br>Membrane-bound HJV is a co-receptor for bone morphogenetic proteins and activates hepcidin<br>Soluble HJV is produced by furin cleavage in hypoxia and iron deficiency and downregulates hepcidin |
| Hemosiderin | Histologic identification of iron stain in tissues |

**TABLE 118-2** Hereditary Hemochromatosis

| Name | Gene | Gene Product | Pattern of Inheritance | Phenotype |
|---|---|---|---|---|
| **HFE-Related HHC** | | | | |
| Type 1 | *HFE,* 6p21.3 | HFE | Autosomal recessive | Variable clinical outcome |
| **Juvenile-Type HHC** | | | | |

HHC, Hereditary hemochromatosis.

on hepatocytes.[18] Hepcidin expression is normally induced by excess iron or inflammation and downregulated by iron deficiency, ineffective erythropoiesis, or hypoxia.[19-21] Persistently high levels of hepcidin are associated with the anemia of chronic inflammation; iron is retained within the enterocytes and macrophages, leading to low transferrin saturation and reduced availability of iron for erythropoiesis. In contrast, inappropriately low hepcidin expression permits increased absorption of iron from the duodenum, high transferrin saturation, and iron overload in sites of tissue storage.

## GENETICS

Four types of HHC have now been described, all of which are linked to gene mutations (Table 118-2). Classic HHC (type 1) is an autosomal recessive disorder caused by mutations of the *HFE* gene located on chromosome 6.[22] The most common mutation is a single amino acid substitution of tyrosine for cysteine at position 282 (C282Y), particularly in people originating from Northern Europe. Homozygosity for this mutation is a risk factor for organ damage as a result of iron overload, although phenotypic expression varies widely. Other mutations of the *HFE* gene include the replacement of histidine with aspartic acid at position 63 (H63D) and the substitution of serine for cysteine at position 65 (S65C). Clinical manifestations of the latter mutations are less significant, although compound heterozygosity may be associated with evidence of iron overload, particularly if comorbid conditions such as excess alcohol intake or steatosis are present.[23,24]

Unlike mutations of the *HFE* gene that may become clinically obvious in middle age, hemojuvelin (HJV-related HHC, type 1A) or hepcidin (HAMP-related HHC, type

2B) mutations result in juvenile HHC (type 2), with evidence of iron overload in the teens or twenties. The affected gene has been mapped to the long arm of chromosome 1.[22] In such cases, the rate of iron accumulation seems to be greater than in adult HHC and is associated with widespread organ involvement and early mortality.[25] In these patients, cardiomyopathy, diabetes mellitus (DM), and hypogonadism are more common than severe liver disease.[22,26] Unlike the association of HHC with people of Northern European ancestry, juvenile HHC has been most frequently reported in Italy.[27] Transferrin receptor (TfR) mutations (TfR2-related HHC, type 3) cause clinical disease similar to classic HFE-related HHC. Such mutations are very rare.[28] Type 4 or ferroportin-related HHC is an autosomal dominant condition that is described in European and Australian families.[29,30] Two types of ferroportin mutations have been reported. In the first type, loss of surface localization of ferroportin results in a decreased ability of cells to export iron, causing iron to build up predominantly in macrophages. In the second type, hepcidin-induced ferroportin dysfunction leads to iron accumulation in parenchymal cells of the liver and other tissues. Phenotypic expression varies, with some patients manifesting the effects of iron overload in a similar manner to classic HHC, and others showing minimal evidence of organ damage.[31]

### Other Inherited Iron-Overload Syndromes

Several other inherited iron-overload syndromes have been described. In people of African descent, a common polymorphism in the ferroportin 1 gene is associated with mild anemia and a tendency to iron loading.[32] Aceruloplasminemia is caused by homozygous mutation of the ceruloplasmin gene and results in anemia, evidence of iron excess, glucose intolerance, and neurologic symptoms.[33] Familial atransferrinemia is an autosomal recessive condition associated with severe anemia in the presence of tissue iron deposition.[34] A number of ferritin mutations have been described that result in hyperferritinemia, some with specific organ damage. Patients with hereditary hyperferritinemia-cataract syndrome have elevated ferritin levels and bilateral congenital cataracts.[35] Neuroferritinopathy is an autosomal dominant movement disorder in which iron preferentially deposits in the brain despite variable serum ferritin levels.[36] In contrast, the entity of benign hyperferritinemia has also been reported, in which, despite a mutation in the coding region of L-ferritin, no clinical manifestations develop.[37]

A congenital form of iron overload is neonatal hemochromatosis in which excess iron deposition results from immune-mediated liver injury and is ameliorated by administration of intravenous Ig during pregnancy.[38]

## EPIDEMIOLOGY

Although HHC was previously thought to be a rare condition, genetic testing has revealed that it is one of the most common heritable disorders. Although 5 out of every 1000 individuals of Northern European origin are homozygous for the *HFE* mutation, phenotypic expression varies, and clinical cases are much fewer in number.[22] In a study of nearly 100,000 individuals from primary care practices in the United States, the prevalence of C282Y homozygosity was as follows: white, 0.44%; Native American, 0.11%; Hispanic, 0.027%; African American, 0.014%; Pacific Islander, 0.012%; and Asian, 0.0004%.[39] Peak age at the time of diagnosis is 40 to 60 years for classic HHC.

## INFLUENCE OF OTHER GENES AND ENVIRONMENT

Clinical manifestations of HHC vary greatly between people with similar mutations, suggesting that other factors influence disease expression. One study demonstrated that among C282Y homozygotes, up to 82% have hyperferritinemia, whereas approximately 28% of males and 1% of females ultimately experience clinical manifestations of HHC—defined as the presence of liver disease, hepatocellular carcinoma, and arthritis of the second and third metacarpophalangeal joints—by age 65 years.[40] In contrast, compound heterozygotes with *C282Y/H63D* mutations exhibit higher serum ferritin and transferrin saturation levels compared with normal control subjects but are at very low risk of clinical HHC.[41]

Other genes may play a role in modifying the phenotypic expression of iron overload. The presence of the gene *CYBRD1*, which encodes duodenal reductase DCYTB, is associated with lower serum ferritin levels in C282Y homozygotes.[42] Furthermore, mutations of other iron-related genes, such as hepcidin, hemojuvelin, haptoglobin, and BMP, may influence disease manifestations.[43-47] In addition, profibrotic genes (e.g., transforming growth factor) may accelerate the onset of cirrhosis in susceptible people.[48]

The reason that HHC disease penetrance is more evident in C282Y homozygote males than females may be explained by recurrent menstrual blood loss and consequent slower accumulation of iron stores in women. However, genetically determined sex differences in ferritin levels may occur because distinct HLA A*03B*07 and A*03B*14 haplotypes have been reported in men and women with clinical evidence of HHC.[49]

Environmental factors, including diet, smoking, alcohol intake, and comorbid diseases, also influence clinical expression of HHC. The metabolic syndrome is associated with insulin resistance–associated iron overload, which, in the presence of HHC, may have a synergistic effect on liver damage.[16] Concurrent liver disease due to hepatitis or steatosis may exacerbate the process of fibrogenesis.[50] In addition to the known toxic effect of alcohol on hepatocytes, it also downregulates hepcidin expression and increases iron absorption, contributing to end-organ damage in patients with innate iron overload.[51,52] Furthermore, meat consumption and high citrus fruit intake also contribute to increased iron loading. However, ingestion of noncitrus fruits may have a protective effect.[53]

## PATHOGENESIS

The clinical expression of HHC may be influenced by several pathophysiologic mechanisms, including increased duodenal absorption of dietary iron; decreased expression of the key regulatory peptide, hepcidin; altered function of the HFE protein; and the direct and indirect toxic effects of iron deposition in target organs.[19] Recent insight has been gained into the function of hepcidin. Human mutations and murine

knockout models of genes for hepcidin, hemojuvelin, TfRs or HFE result in reduced hepcidin levels and increased duodenal iron absorption.[54] The HFE protein also plays a role, and it has been suggested that interactions between HFE and TfR-1 and -2 influences hepcidin expression by acting as a hepatocyte membrane-based iron sensor.[55]

Chronic iron overload is thought to cause tissue damage by several mechanisms, including impairment of mitochondrial function and weakening of lysosomal membranes with consequent discharge of enzymes into the cytoplasm.[56] Increased free radical formation contributes to lipid peroxidation of cell membranes, and profibrogenic cytokines are released.[19] The extent and duration of iron deposition correlate with the development of fibrosis, and it is thought that substantial hepatocyte and Kupffer cell iron accumulation precedes organ damage.[16] In HHC, iron first accumulates in parenchymal cells, with reticuloendothelial (RE) involvement a late feature, in contrast to transfusional iron overload, in which RE cells are primarily targeted. Values of serum ferritin exceeding 1000 μg/L are associated with significantly increased risks of liver fibrosis and cirrhosis.[7,19,57]

## CLINICAL FEATURES

### Extra-Articular Manifestations

HHC presents more commonly in men than in women and typically manifests in middle-aged adults when iron stores gradually accumulate, often reaching 20 to 30 g.[19,40] The classic findings of hepatic abnormalities, skin pigmentation, arthritis, DM, erectile dysfunction, heart enlargement, and/or conduction defects indicate late disease.[58] Organ involvement varies and is unpredictable, although the liver, as the major site of iron storage, is usually affected. Not infrequently, abnormalities of liver enzymes, checked as part of a routine health check, identify the problem.[59] However, with the recent availability of genetic testing, presentation by asymptomatic relatives of probands is now more common.

In the liver, increasing iron deposition results in eventual fibrosis and cirrhosis. It is worth noting that some patients with HHC and iron overload may progress to fibrosis even in the presence of normal levels of serum transaminases.[60] Therapeutic phlebotomy can cause regression of some of these changes, particularly in early disease.[61] Additional causes of significant liver disease are common in patients with HHC and may contribute to hepatocellular damage.[60] In people with established cirrhosis, the risk of malignant hepatoma is 20-fold greater than the general population, with a higher risk in affected men than women.[62,63]

Iron deposition in the heart can result in conduction system abnormalities and heart failure. Several large population studies of HHC and atherosclerosis have failed to find a link. However, elevated ferritin levels, particularly in the setting of nonalcoholic fatty liver disease, may be associated with vascular damage via hepcidin upregulation.[64-66] Glucose intolerance tends to be a late finding in HHC and is due to progressive iron accumulation in pancreatic β cells, causing low C-peptide and insulin levels.[67] α Cell function is usually preserved, and serum glucagon levels are normal or increased. In patients with HHC who present symptomatically, DM has been noted in approximately 50%. However, for patients with HHC who have early insulin resistance and no evidence of cirrhosis, venesection may reverse iron deposition–induced β cell dysfunction.[68,69] The risk of DM is higher in C282Y heterozygotes with no clinical evidence of HHC compared with control subjects.[70,71]

Pituitary involvement in HHC is due to iron deposition causing reduced serum levels of secreted hormones, mainly from the anterior aspect of this gland, resulting in loss of libido and erectile dysfunction.[72,73] Primary hypogonadism from testicular iron overload is much less common.[74] Therapeutic phlebotomy may reduce these symptoms, particularly in younger men.[75] Hypothyroidism in HHC is thought to be due to a direct toxic effect of iron on thyroid cells and is associated with low thyroxine and elevated thyroid-stimulating hormone.[76] Such endocrine abnormalities may contribute to the development of osteoporosis in these individuals.

Skin discoloration occurs as a result of extra melanin and iron in the epidermis. It is a late finding, and the development of "bronze diabetes" represents the end stage of years of iron accumulation in the tissues.

Patients with HHC have increased susceptibility to certain infections. High serum iron concentrations may increase bacterial virulence, and excess iron in macrophages is thought to reduce phagocytosis.[77] Particular caution is advised with uncooked seafood because of the risk of septicemia from *Vibrio vulnificus*. In addition, *Yersinia enterocolitica*, *Listeria monocytogenes*, *Salmonella enteritidis* serotype *typhimurium*, *Klebsiella pneumoniae*, *Escherichia coli*, *Rhizopus arrhizus*, and *Mucor* species all have been reported to cause severe illness in patients with iron overload.[9]

Apart from the increased risk of malignant hepatoma in patients with established cirrhosis, an independent association of nonhepatic cancers, particularly breast and colorectal tumors, in HFE C282Y homozygotes has been reported.[78] H63D homozygosity confers a threefold increased risk of colorectal cancer in carriers of the MMR gene mutation.[79] Iron is potentially carcinogenic via several mechanisms, including its immunosuppressive properties and its role as an essential cofactor for tumor cell growth and in catalyzing the formation of hydroxyl radicals. Furthermore, cancer risk is lower with reduced iron stores.[80]

### Articular Features

Arthralgia/arthritis is a common presentation in HHC, affecting 50% to 80% of patients and significantly interfering with quality of life.[81-87] Although it tends to be a late feature, joint pain nevertheless may be the presenting symptom of HHC, alerting a diligent physician to the presence of an underlying metabolic disorder. Articular involvement may be widespread, but changes to the second and third metacarpophalangeal joints are most characteristic[87] (Figures 118-1A and B). Arthritis may be present in the proximal interphalangeal joints, wrists, shoulders, hips, knees, and ankles.[86] Patients notice pain and stiffness of the involved joints, but clinical evidence of synovitis is usually absent. Hip damage develops in approximately 25% of people with HHC, and after hip arthroplasty, the risk of aseptic loosening of the prosthesis is increased.[88,89] The differential diagnosis of HHC-related arthropathy includes severe osteoarthritis, rheumatoid arthritis, other forms of

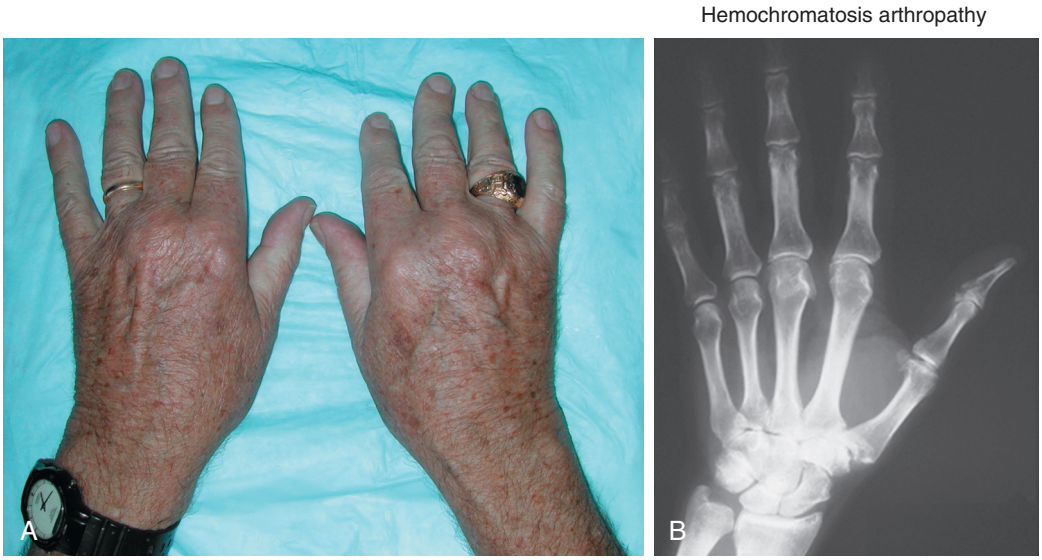

**Figure 118-1** Arthritis of the second and third metacarpophalangeal joints, characteristic of hereditary hemochromatosis.

inflammatory arthritis, and crystal arthritis. Rheumatoid factor is typically negative, however, and in established cases, radiographs show distinctive findings, such as joint space narrowing of the second and third metacarpophalangeal joints, hook-like osteophytes on the radial aspect of the metacarpal heads, and chondrocalcinosis, particularly of the triangular fibrocartilage adjacent to the ulnar styloid. HHC-related arthritis is more common in male C282Y homozygotes than in other genotypes.[7]

The pathogenetic mechanisms underlying HHC-related arthritis are unknown, and the prevalence of joint pain in this condition has not been found to correlate with body iron stores. Toxic effects from local iron deposition, acceleration of cartilage defects, and immunologic mechanisms have been implicated.[83,84,90] Under light microscopy, the involved synovium demonstrates iron deposits, particularly in the lining cells, but inflammatory cell infiltration is not typical.[91-93] Neutrophil infiltration of the synovial sublining layer has been described.[94] Apatite and calcium pyrophosphate dihydrate crystals may be observed, but it is not known why they are preferentially expressed in HHC. In association with the increased incidence of calcium pyrophosphate dihydrate deposition disease in HHC, a putative role for a parathyroid hormone fragment (PTH 44-68) has been suggested.[95] Joint symptoms due to HHC tend not to improve after therapeutic phlebotomy.

## DIFFERENTIAL DIAGNOSIS

Because of the lack of a physiologic mechanism to enhance iron excretion, the inevitable result of increased iron absorption is iron overload, which may be due to inherited defects in iron metabolism, as previously described, or secondary to other causes (Table 118-3). A full history of medication use, including over-the-counter iron tablets, and a review of any blood transfusions should be elicited. Ineffective erythropoiesis in conditions such as the thalassemias or sideroblastic anemia also results in the buildup of iron stores. Porphyria cutanea tarda (PCT) is associated with hyperferritinemia, high transferrin saturation levels, and an increased incidence of *HFE* mutations.[96] However, the clinical findings, particularly dermatologic findings, distinguish this disease from HHC. Elevated ferritin levels may result from severe inflammation. IL-6 is a potent stimulator of hepcidin via the STAT3 pathway, resulting in reduced iron absorption and elevation of tissue and serum ferritin levels, although these changes are accompanied by low transferrin saturation.[97] Chronic liver disease resulting from hepatitis, alcohol

excess, or fatty infiltration is associated with hyperferritinemia and normal or elevated transferrin saturation values.[98] Alcohol, independent of liver damage, induces ferritin synthesis and iron overload in people who consume more than two alcoholic drinks per day.[63,99]

## DIAGNOSTIC TESTS

A high index of suspicion is helpful when a patient presents with joint pain and abnormal liver enzymes. Although the differential diagnosis is wide, the presence of elevated ferritin and transferrin saturation levels (serum iron × 100/total iron-binding capacity) strongly points to the answer. Serum iron should be measured with the patient fasting because concentrations may be increased after a meal. High ferritin levels also may be caused by systemic inflammation or malignancy, but these conditions tend to be associated with reduced transferrin saturation. Other causes of elevated transferrin saturation include high serum iron as a result of hepatic cytolysis or low transferrin levels as a result of liver failure, and these possibilities should be excluded. If ferritin measures greater than 200 μg/L and transferrin saturation is greater than 45%, genetic screening is recommended. The finding of homozygosity for the C282Y mutation or compound heterozygosity for C282Y/H63D confirms the diagnosis. However, if these mutations are not present and evidence of iron overload exists, investigation for more rare genetic defects, such as alterations of the genes that encode hemojuvelin, hepcidin, TfR2, or ferroportin, can be considered in the context of the pertinent clinical features (see Table 118-2).

A liver biopsy may be considered for prognostic purposes in established cases. Patients most likely to show evidence of cirrhosis are those who have the combination of a ferritin level greater than 1000 μg/L, elevated transaminases, and thrombocytopenia.[57,100] In contrast, patients with a serum ferritin level less than 1000 μg/L and no additional risk factors for liver disease are unlikely to have cirrhosis. A liver biopsy is therefore considered for those with advanced disease or if the diagnosis is in question, particularly in people with evidence of iron overload who are HFE negative. HHC can be distinguished histologically from alcoholic cirrhosis by the preferential distribution of iron in the hepatocytes in the former and in the Kupffer cells in the latter.[101] MRI of the abdomen also can be used to determine iron overload in the internal organs. Gradient T2-weighted sequences show decreased signal intensity and correlate highly with liver iron concentrations.[102,103] This imaging method also can identify other locations of iron deposition (e.g., in the spleen, pancreas, lymph nodes, and heart). Because HHC is a systemic condition, other investigations should include a search for diabetes, thyroid disease, hypogonadism, osteoporosis, and cardiomyopathy. Disease mimickers, such as PCT, ineffective erythropoiesis, chronic alcohol excess, and the metabolic syndrome should be excluded.

## SCREENING

Greater disease awareness and the availability of genetic screening have meant that HHC is now likely to be diagnosed before the classic triad of cirrhosis, DM, and skin hyperpigmentation develops. However, late presentation can occur, particularly in people with additional risk factors for iron overload or liver disease. For individuals in whom genetic testing has identified a risk for HHC, but with no clinical evidence of disease, yearly biochemical screening is recommended, measuring serum ferritin, transferrin saturation, and liver enzymes. Such monitoring facilitates early detection of organ compromise and timely initiation of treatment.

### Population Screening

HHC is an attractive target for population screening because of its high prevalence, potential disease severity, availability of cost-effective treatment, and impact of early diagnosis on the morbidity and mortality of affected patients. However, the clinical penetrance of HHC is low and the negative consequences (e.g., insurance related and psychological) of finding an associated gene mutation in an asymptomatic person without any evidence of disease would be considerable. General screening for HHC is therefore not recommended.[19,102,104]

### Screening People with a Positive Family History

Individuals with a first-degree relative who has been diagnosed with HHC should be tested for *HFE* mutations and evidence of iron overload.[19] For children of a patient with HHC, it is recommended that the other parent be screened first, because offspring will be affected only if both parents carry a relevant mutation. In first-degree relatives of C282Y homozygotes, the degree of iron overload is associated with disease severity in the proband.[105] The risk of clinically relevant iron toxicity is extremely low for people who are found to have C282Y or H63D heterozygosity. Infrequently, H63D homozygosity is associated with mild iron excess.[24]

### Screening in Patients with Related Diseases

The European Association for the Study of Liver Diseases has recommended HFE testing in patients with unexplained chronic liver disease and raised transferrin saturation levels (see Figure 118-2). Furthermore, HFE testing should be considered in people with PCT, well-defined chondrocalcinosis, and hepatocellular carcinoma and those with late-onset type 1 DM because C282Y homozygosity has a higher prevalence in these conditions.[102] HHC-related genotypes are a risk factor for the development of liver disease in the presence of significant comorbid illness, particularly chronic infectious hepatitis, PCT, or steatosis.[19,106]

## TREATMENT

Removal of iron from the body can be undertaken by phlebotomy, erythrocytapheresis, or the use of iron chelators. Treatment is divided into the "depletion" stage, which aims to reduce ferritin levels to normal, and the "maintenance" stage, in which the frequency of iron removal is decreased and ferritin levels are monitored. Some, but not all, consequences of iron deposition are reversed by removing iron. Most patients note an improvement in well-being and skin

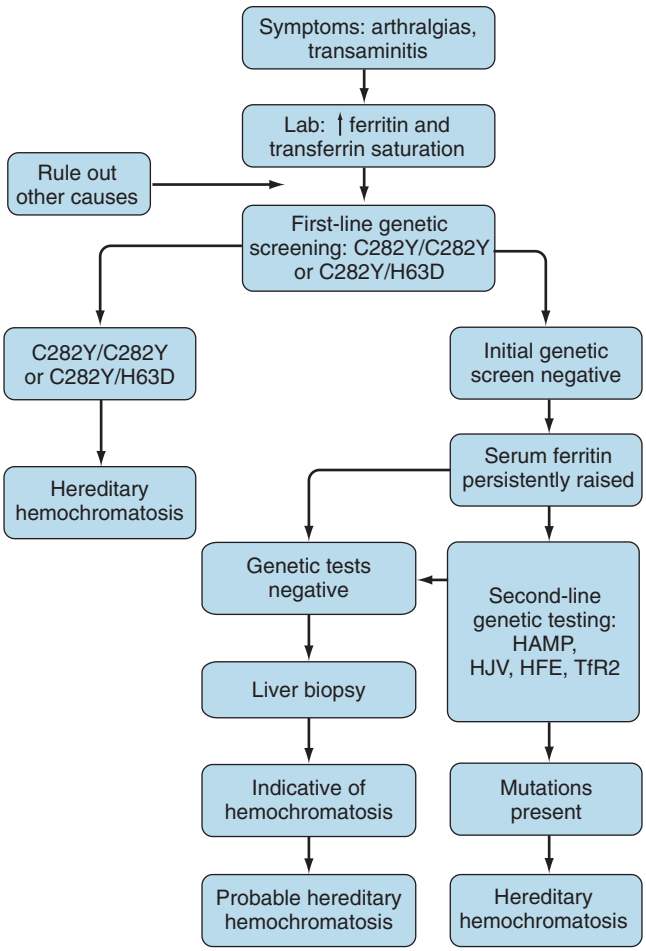

**Figure 118-2** Algorithm for the diagnosis of hereditary hemochromatosis.

pigmentation; furthermore, amelioration of cardiac function and glucose control, in addition to hepatic fibrosis, has been documented.[61,102] However, symptoms of arthritis do not change, and established cirrhosis is irreversible.[19]

Phlebotomy is the mainstay of treatment for iron overload in the setting of HHC. Every 500 mL of whole blood contains up to 250 mg of iron, and thus it can take more than 1 year for iron stores to normalize with weekly venesection. It is recommended that treatment be started when serum ferritin levels are consistently and progressively above normal local reference ranges.[104] Weekly phlebotomy of 500 mL of blood should be guided by ferritin and hemoglobin/hematocrit levels, aiming for serum ferritin of 50 µg/L in the absence of anemia. Transferrin saturation levels are not an accurate measure of therapeutic efficacy because they are relatively resistant to change in iron stores in C282Y homozygotes.[107] In the maintenance phase, the frequency of venesection depends on the response to treatment. Anemia should be avoided because it may trigger further lowering of hepcidin levels and encourage intestinal iron absorption.[104] Although generally safe and well tolerated, adverse effects of blood removal in HHC include cardiac arrhythmias that may develop during rapid mobilization of iron stores.[108] Vitamin C supplementation may exacerbate such problems by facilitating iron release and increasing pro-oxidant and free radical activity.[19,108,109] In many countries, therapeutic phlebotomy from patients with HHC may contribute to the blood donation pool.[102,107]

Erythrocytapheresis removes more red blood cells per session than phlebotomy and preserves platelets, plasma proteins, and coagulation factors.[110] The target of normal iron levels is achieved more rapidly with this technique in comparison with phlebotomy, but the financial costs are greater. The additional technical expertise means that erythrocytapheresis is not commonly used to treat iron overload in individuals with HHC.[107]

Iron chelators may be administered orally (e.g., deferasirox) or parenterally (e.g., deferoxamine). However, these drugs are associated with more adverse effects than phlebotomy and thus are reserved for patients who are intolerant of regular venesection.[107,111] Proton pump inhibitors (PPIs) can potentially contribute to reduced iron absorption because reduced gastric acid secretion lowers the solubility of inorganic iron, thereby decreasing its absorption. Furthermore, they may influence iron uptake into red blood cells, a process that requires proton cotransport.[107] However, currently no evidence shows that chronic use of PPIs significantly affects iron levels in patients with HHC.

High doses of vitamin C facilitate iron release and increase pro-oxidant and free radical activity.[19,108,109] Therefore patients with HHC should not take extra vitamin C but can continue to eat fresh produce containing this substance. Other dietary recommendations include reduction or avoidance of food containing high doses of iron, such as red meat and internal organs. Uncooked shellfish is a particular hazard because of the risk of contamination with *V. vulnificus*.[112] Some alcoholic drinks contain iron, and all are potentially hepatotoxic. Alcohol should be consumed only occasionally because it seems to have a synergistic effect in the presence of iron overload on the development of cirrhosis and hepatocellular carcinoma.[113] Maintenance of normal body weight is important to avoid the hepatic damage associated with steatosis.

Just as the pathogenesis of joint pain in HHC is unclear, treatment of arthritis in this condition is unsatisfactory, and joint symptoms may progress despite effective phlebotomy. NSAIDs, colchicine, and intra-articular corticosteroids may be helpful in some cases. Osteoporosis is a potential disease complication, particularly in the setting of hypogonadism or reduced thyroid function. Hormone replacement, if indicated, should be instituted, although some patients may require additional treatment with calcium and bisphosphonates.

Although animal studies suggest that iron overload contributes to an overall risk of carcinogenesis, little epidemiologic information to date suggests that this phenomenon applies to humans with HHC. Nevertheless, age-appropriate screening for malignancy may be considered in the holistic approach to such patients.[114]

## OUTCOME

The earlier HHC is diagnosed, the better is the prognosis, because morbidity and mortality are directly related to the extent of iron overload and consequent organ compromise. The absolute risk of liver damage is approximately 5% in

homozygous males and 1% in females.[115] However, the development of cirrhosis is a serious indicator of reduced longevity. For patients with HHC-related hepatic failure who undergo liver transplantation, survival rates are lower compared with people who receive liver transplants for other reasons. Post-operative death in these circumstances is typically due to cardiac complications or infection.[116]

In the absence of cirrhosis or diabetes, patients with HHC have a normal life expectancy.[104] Given the importance of timely recognition of this common metabolic problem, a vigilant physician can make an enormous difference in the lives of patients who present with early symptoms of this disease. In this context, the rheumatologist has a particularly relevant role in keeping a high index of suspicion for the diagnosis of HHC in patients with atypical osteoarthritis or chondrocalcinosis.

## CONCLUSION

Cost-effective screening focused on people at greatest risk of clinical disease, in association with a high level of diagnostic suspicion in patients with relevant symptoms and signs, should reduce the number of patients presenting with irreversible organ damage from HHC. In addition, greater understanding of the genetic and environmental modifiers of clinical disease expression may help to delay or mitigate the consequences of iron overload in susceptible individuals. How comorbid disease influences the onset and extent of disease is particularly relevant in the context of the growing numbers of patients with obesity, metabolic syndrome, and hepatic steatosis. Although phlebotomy has been the mainstay of treatment for many years, exact targets for iron stores and ferritin levels warrant further investigation. New chelators are under review, and the development of hepcidin peptides/agonists, which may be able to correct the physiologic deficit linked to increased iron absorption and deposition, hold promise for the future and may contribute to our understanding of clinical penetrance in patients with genetic susceptibility to iron overload.[104] In the meantime, the predictive value of symptom combinations in relevant people may influence screening guidelines and facilitate a cost-effective way of reducing the disease burden in populations at risk of HHC.[13]

CHAPTER 119

# Hemophilic Arthropathy

Lize F.D. van Vulpen • Goris Roosendaal • Roger E.G. Schutgens • Floris P.J.G. Lafeber

**KEY POINTS**

- The most common rheumatologic complication in severe hemophilia is hemophilic arthropathy, which mainly affects the elbows, knees, and ankles.
- A combined cascade of degenerative and inflammatory processes initiated by recurrent joint bleeds leads to hemophilic arthropathy.
- Other musculoskeletal complications of hemophilia are muscle and soft tissue hemorrhage, chronic synovitis resulting from the inflammatory processes, pseudotumors, and osteoporosis.
- Treatment aims at prevention of recurrent hemarthrosis through prophylactic factor replacement therapy.
- If conservative measures fail, orthopedic surgery, including total joint replacement, is indicated and can be performed safely with clotting factor replacement therapy.

Spontaneous joint bleeding is a characteristic manifestation of the inherited coagulation disorder hemophilia,[1] but such bleeding also can occur as a consequence of other bleeding disorders such as von Willebrand disease,[2] as a complication of anticoagulant treatment,[3] or upon experiencing trauma[4] or undergoing major joint surgery.[5] Irrespective of the underlying cause, hemarthrosis can lead to significant joint tissue damage and subsequent major morbidity.

Hemophilia is an X-linked recessive coagulation disorder caused by deficiency of coagulation factor VIII (hemophilia A) or factor IX (hemophilia B; Christmas disease). Hemophilia has an estimated frequency of 1 in 5000 to 10,000 male births,[6,7] with approximately 80% to 85% representing hemophilia A. The lack of clotting factor activity leads to inadequate thrombin generation and a tendency for bleeding to occur. The clinical phenotype is strongly correlated with the amount of clotting factor present, expressed as a percentage compared with normal clotting factor activity in blood. Patients with severe hemophilia have less than 1% clotting factor activity, whereas patients with moderate and mild hemophilia have clotting factor activity of 1% to 5% and 5% to 40%, respectively.[8] Spontaneous bleeding mainly affects patients with severe hemophilia; it occurs less frequently in individuals with moderate hemophilia, and patients with mild hemophilia experience bleeding only after sustaining a major trauma or undergoing surgery. The phenotype is also affected by several other mechanisms, including genetic factors, age at the first episode of joint bleeding, and concomitant thrombotic factors.[9,10] In individuals with severe hemophilia, 70% to 80% of all bleeding events occur in the joints, spontaneously as well as in response to stress or trauma.[11,12] The predilection for bleeding in the joint compared with other tissue sites might be caused by the relatively low expression of tissue factor, which is the initiator of the coagulation cascade,[13,14] together with a high level of tissue factor pathway inhibitor in the normal joint[15] and increased local fibrinolysis in the hemophilic joint.[16] On the other hand, mechanical factors damaging the richly vascularized synovial tissue, specifically after being triggered after a first joint bleed, might be causative in this respect.[17]

Musculoskeletal bleeding and treatment-related complications are the most important complications in hemophilia. Development of alloantibodies directed against administered clotting factor (inhibitors) is common, and the transmission of blood-borne virus infections as a result of the use of plasma-derived products in the 1980s caused major morbidity.

## CLINICAL FEATURES

Bleeding into the musculoskeletal system causes a spectrum of clinical features with involvement of joint, muscle, and bone. The distribution of the most affected joints and muscles is shown in Figure 119-1.

### Acute Hemarthrosis

Nearly all patients with severe hemophilia and half of patients with moderate disease activity experience hemarthroses. The most affected joints are the large synovial joints, especially the ankles, knees, and elbows.[12] The hips and shoulders are affected to a lesser extent, and bleeds in smaller joints are rare. In individuals with severe hemophilia the first joint bleed often occurs when they begin walking or running, at a median age of 1.8 years.[10] At this age, early signs of bleeding include irritability and decreased use of the affected limb. Older children and adults frequently describe the onset of a joint bleed as a tingling sensation and tightness within the joint, followed by rapid swelling, loss of range of motion (ROM), pain, and warmth of the skin over the joint.[1] Flexion is the most comfortable position, and disuse (i.e., preventing movement to avoid pain) can cause secondary muscle spasm. Pain rapidly

reduces after clotting factor replacement, with full recovery of joint function within 8 to 24 hours.

Joint bleeds often have a migratory pattern, moving from one joint to the other.[12] A so-called "target joint" develops in about 25% of patients with severe hemophilia—that is, a joint that is more susceptible to subsequent bleeds compared with other joints. It is defined as a joint in which three or more hemarthroses have occurred in the prior 6 months.[17,18] Nowadays, in youngsters with hemophilia, the target joint mostly involves the ankle joint rather than the elbow or the knee, with the latter most commonly affected before the introduction of prophylactic clotting factor replacement therapy.

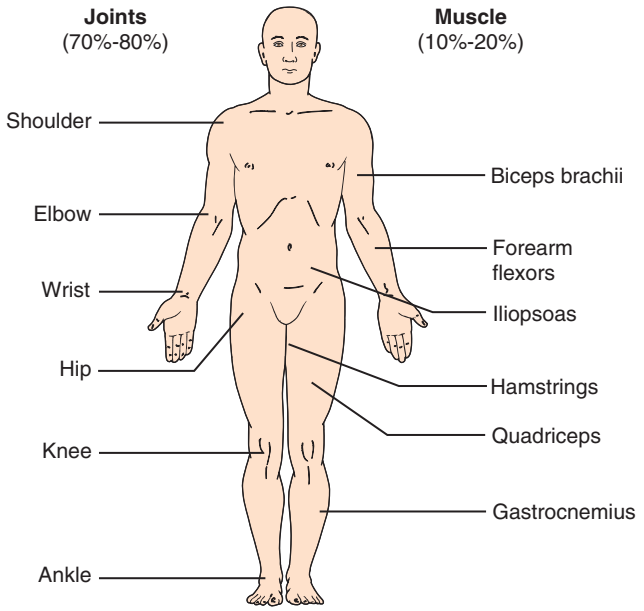

**Figure 119-1** Joints and muscles commonly affected by bleeding in hemophilia. Besides hemarthrosis and muscle bleeding, 5% to 10% of the episodes consist of other major bleeds (e.g., mucous membranes and gastrointestinal), and fewer than 5% of the bleeds occur in the central nervous system.

## Synovitis

Recurrent bleeding into a joint can lead to a vicious circle in which the synovial tissue is unable to remove blood remnants completely, triggering synovial inflammation and proliferation.[19,20] It also induces the development of a rich network of new, fragile blood vessels underneath the synovial tissue, making the joints vulnerable to subsequent (repeated) bleeding.[21] In this condition the joint appears swollen but usually not tense, is often painless, and is only slightly warm. In early stages of synovitis, ROM is preserved, but in chronic stages a mild limitation and flexion deformity can develop. Administration of clotting factor is considered necessary to break the self-perpetuating cycle of hemarthrosis-synovitis-hemarthrosis and to prevent the progressive degeneration of the joint. In contrast to its effect on acute hemarthrosis, clotting factor replacement does not modify the clinical findings immediately, and long-term treatment is indicated.[1]

## Hemophilic Arthropathy

Ultimately, recurrent joint bleeding may lead to hemophilic arthropathy (Figure 119-2). The number of hemarthroses required to cause irreversible damage is unknown and is likely to differ between patients. Progressive degeneration of cartilage, synovial inflammation, and bone changes cause chronic pain, joint stiffness, and a severely limited ROM. Without proper physiotherapy it is often accompanied by muscle weakness and contractures. Joint deformity, subluxation, joint laxity, malalignment, and spontaneous arthrodesis develop in the most severe cases. Physical activity and quality of life are severely affected by hemophilic arthropathy.[22] Progressive synovial fibrosis decreases the frequency of hemarthroses in end-stage arthropathy.

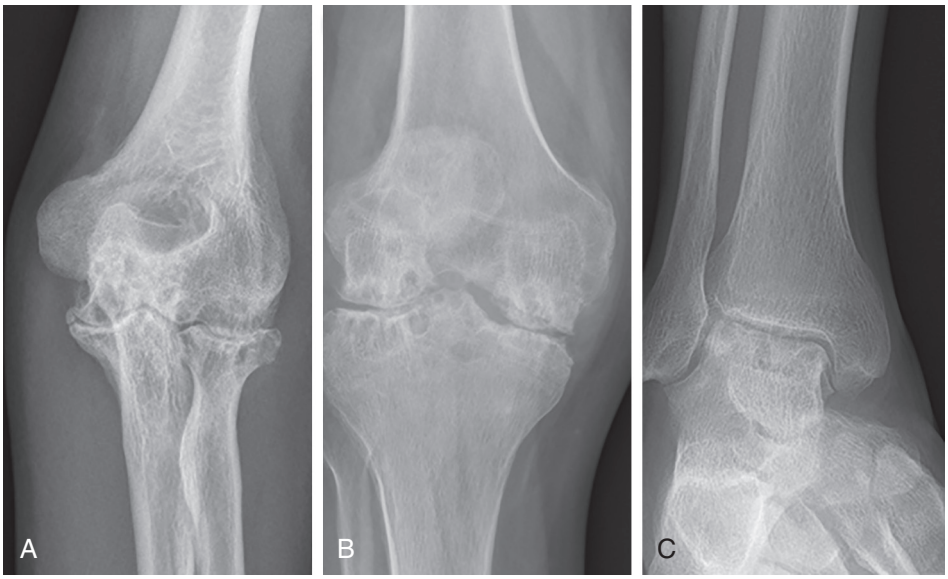

**Figure 119-2** Radiographic changes of hemophilic arthropathy in a 30-year old patient with severe hemophilia. **A,** Left elbow. **B,** Right knee. **C,** Right ankle. All of the radiographs show joint space narrowing and subchondral cysts, which are most pronounced in the elbow and knee.

### Muscle and Soft Tissue Hemorrhage

The muscle is the second most common site of bleeding in individuals with hemophilia, accounting for approximately 10% to 20% of bleeds.[1] The bleeding usually results from a direct blow or sudden stretch and can occur in any muscle of the body. The clinical features depend on the muscle involved, but overall muscle bleeding emerges more insidiously than do hemarthroses, and prodromal symptoms are rare. A tender swelling in the muscle with severe pain upon stretching or active contraction rapidly progresses into protective spasm and a flexed position. Physical examination shows a palpable tender hematoma with swelling, warmth, and bruising. Bleeding into deeper compartments can be difficult to diagnose because visible symptoms are lacking. An iliopsoas hemorrhage usually presents with pain in the lower abdomen, groin, and/or lower back, with pain on extension but not rotation of the hip.[23] A life-threatening complication of ongoing bleeding is compartment syndrome with femoral neuropathy and possible muscle necrosis. Other sites of muscle bleeding associated with neuropathy are the posterior compartments of the lower leg and the flexor group of the forearm. Muscle hemorrhage can result in permanent contracture, rebleeding, and the formation of pseudotumors.[24]

### Pseudotumor

The formation of pseudotumors is a rare but serious complication unique to hemophilia that mainly occurs after inadequate replacement therapy or after development of an inhibitor. Repeated and unresolved muscle bleeding or a progressive subperiosteal hemorrhage causes an expanding encapsulated and calcified hematoma with radiographic features mimicking tumor-like conditions; hence, they are called pseudotumors (Figure 119-3).[1,25] Progressive enlargement of the pseudotumor can lead to erosion of the adjacent bone, compression of neurovascular structures, spontaneous rupture, fistula formation, and pathologic fractures. Pseudotumors have two distinct pathologic forms. In adults, pseudotumors occur proximally, (mainly in the pelvis or femur) expand slowly, and usually require surgical excision. In contrast, pseudotumors affecting young patients occur distal to the elbow or knee, result from direct trauma, develop rapidly, and often are amenable to conservative treatment with immobilization and factor replacement.[26]

### Osteoporosis

Patients with hemophilia have a significantly lower bone mineral density compared with age-matched control subjects.[27] The pathogenesis is multifactorial, with several predisposing factors occurring frequently in the hemophilic population: reduced weight-bearing activity, arthropathy, muscle atrophy, a lower body mass index, presence of an inhibitor, and the influence of blood-borne virus infections and their treatment.[28,29] To maintain bone mass, weight-bearing activities should be promoted and supplementation of calcium and vitamin D in selected cases should be considered.[1]

## DIAGNOSIS

In the majority of patients, the diagnosis "hemophilia" is made in the presence of a positive family history. Up to one-third of the patients have a negative family history, and the disease is the result of a de novo germline mutation, but somatic mosaicism in a (grand)parent also has been described.[30,31] Clinical features raising suspicion of hemophilia are easy bruising in early childhood, spontaneous bleeding (particularly into the joints, muscles, and soft tissues), and excessive bleeding after trauma or surgery. Screening tests in patients with a bleeding diathesis of unknown cause include platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT). Individuals with hemophilia characteristically have a normal platelet count, normal PT, and a prolonged aPTT, although the aPTT might be near normal in individuals with mild hemophilia. Specific clotting factor assays are performed to determine the type and severity of hemophilia and to distinguish it from von Willebrand disease. The diagnosis can be confirmed by DNA-based techniques. Given the rarity and complexity of the disease, a doctor specializing in hemostasis should be consulted.

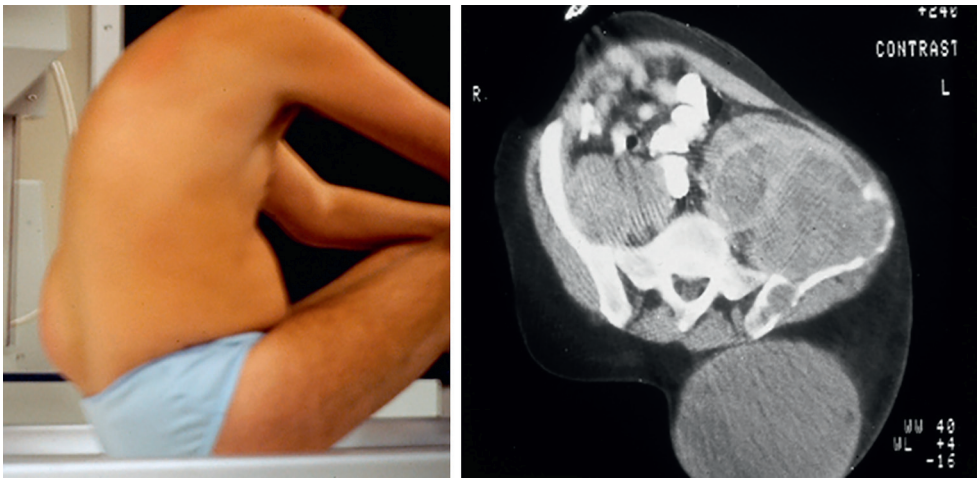

**Figure 119-3** A pseudotumor invading the left wing of the ilium in a patient with severe hemophilia and an inhibitor.

Frequent monitoring of musculoskeletal status is indicated in patients with hemophilia to diagnose complications at an early stage because prevention is the cornerstone of treatment. Use of physical examination assessment tools can help identify subtle early signs of joint damage, monitor joint health over time, and evaluate treatment efficacy. Several hemophilia-specific instruments have been developed and validated.[32-34]

Clinical assessment of the musculoskeletal system at the time of an acute bleed should include evaluation of warmth, bruising, swelling, tenderness, muscle tone, pain, ROM, gait, and function.[1,35]

## Conventional Radiography

Conventional radiology is most frequently used for imaging in hemophilia and is mainly suitable for late osteochondral changes. Radiologic classification of hemophilic arthropathy is usually performed via the Pettersson score (Table 119-1).[36] This additive scoring system is based on assessment of the knees, ankles, and elbows, with eight criteria being scored: osteoporosis, epiphyseal enlargement, irregularity of the subchondral surface, joint space narrowing, subchondral cyst formation, erosion of joint margins, incongruence of the articulating bone ends, and joint deformity. The Pettersson score correlates well to function[37] but is only able to diagnose late arthropathic changes. Typically it is used to evaluate progression of arthropathy and for planning of arthrodesis or joint replacement. It has been discussed whether digital scoring systems are more objective and have a higher interobserver variability than the Pettersson method. Digital analysis of hemophilic arthropathy of the knee is feasible,[38] but adaptation for the specific characteristics of hemophilic arthropathy is necessary.

Radiography has poor sensitivity in demonstrating early soft tissue changes that occur before irreversible cartilage and bone damage. Acute hemarthrosis shows as joint effusion and displacement of fat pads, but it is difficult to distinguish effusion from synovial hyperplasia.

**TABLE 119-1** Pettersson Score[36]

| Joint: Elbow/Knee/Ankle | | Score |
|---|---|---|
| Osteoporosis | Absent<br>Present | 0<br>1 |
| Enlargement of epiphysis | Absent<br>Present | 0<br>1 |
| Irregularity of subchondral surface | Absent<br>Partially involved<br>Totally involved | 0<br>1<br>2 |
| Narrowing of joint space | Absent<br>Joint space >1 mm<br>Joint space <1 mm | 0<br>1<br>2 |
| Subchondral cysts formation | Absent<br>1 cyst<br>>1 cyst | 0<br>1<br>2 |
| Erosion of joint margins | Absent<br>Present | 0<br>1 |
| Gross incongruence of articulating bone ends | Absent<br>Slight<br>Pronounced | 0<br>1<br>2 |
| Joint deformity (angulation and/or displacement) | Absent<br>Slight<br>Pronounced | 0<br>1<br>2 |
| Total (maximum 13 points per joint) | | |

Radiographs of the six index joints (both knees, both ankles, and both elbows) are scored separately. The sum of these scores, with a maximum of 78 per patient, is the Pettersson score.

## Magnetic Resonance Imaging

As prophylactic treatment improves and joint damage diminishes, more sensitive MRI has obvious advantages compared with radiography in evaluating treatment efficacy. MRI enables visualization of small alterations, such as hemosiderin depositions, synovial hypertrophy, and minor cartilage damage without joint space narrowing.[39] The clinical implications of small changes, especially in the absence of reported joint bleeds, remains to be established,[40] but as in osteoarthritis (OA), it may be predictive of subsequent rapid progressive damage. MRI can also provide more detailed information about advanced changes, such as erosions, subchondral cysts, and cartilage destruction. It is valuable in detailed evaluation of a pseudotumor, synovitis, or diagnosis and follow-up of a hemorrhage in deeper compartments (e.g., the abdomen and iliopsoas). Widespread use of MRI is restrained by its costs, availability, and requirement of sedation in young children.

## Ultrasonography

With ultrasonography becoming increasingly standard in rheumatology practices, it is possible to diagnose joint effusion, synovial hypertrophy, abnormalities involving osteochondral surfaces, pseudotumors, and acute hemarthroses.[39,41] Ultrasonography is less costly than MRI, is readily available, does not require sedation in young children, and enables dynamic investigation such as assessment of vascularity of a pseudotumor. Disadvantages are the interobserver variability, complexity of image analyses, difficulty in identifying changes in deeper structures, and a lack of validated scoring systems for hemophilic arthropathy.

## Biochemical Markers

In the field of OA and rheumatoid arthritis (RA), considerable effort is directed toward the identification of biochemical markers in blood and/or urine that can assist in diagnosis, prognosis, and response to treatment.[42] Such markers are as yet sparsely used in clinical trials and still are not used in clinical practice. Also, in the field of hemophilic arthropathy, such markers may become helpful in identifying the tissue-destructive activity of a joint bleed.[43,44]

# PATHOGENESIS

Although it is clear that the presence of blood has devastating effects on the joint, the exact pathogenetic mechanisms of hemophilic arthropathy, and in particular the earliest changes induced by acute hemarthrosis, are not completely understood. Surgical specimens of end-stage arthropathy in patients with hemophilia, together with in vitro experiments and animal models, have indicated that

two major processes are involved: synovial inflammation and cartilage degeneration (Figure 119-4).[20,45] In this respect, hemophilic arthropathy has characteristics of both the RA and the OA joint (Figure 119-5).[46]

## Synovial Inflammation and Proliferation

Synovial tissue is highly vascularized, and in hemophilia even minimal forces can lead to hemarthroses. Filling of the joint space with blood leads to an influx of inflammatory cells into the synovial tissue. Synoviocytes and invading macrophages evacuate blood from the joint cavity completely over a period of 3 to 4 weeks.[17] Four hours after the induction of hemarthrosis, erythrophagocytosis already can be observed.[47] Adaptive changes in the expression of iron regulation proteins in the synovium of patients with hemophilia after repeated joint bleedings are demonstrated.[48] With successive hemarthroses the synovial capacity is overloaded and blood remnants, especially iron, accumulate as hemosiderin depositions in synovial tissue and even cartilage.[19] The presence of iron triggers an inflammatory response and stimulates proliferation of synoviocytes (Figure 119-6). Pro-inflammatory cytokines, including IL-1β, IL-6, and TNF, are produced by the iron-laden synoviocytes.[19,46]

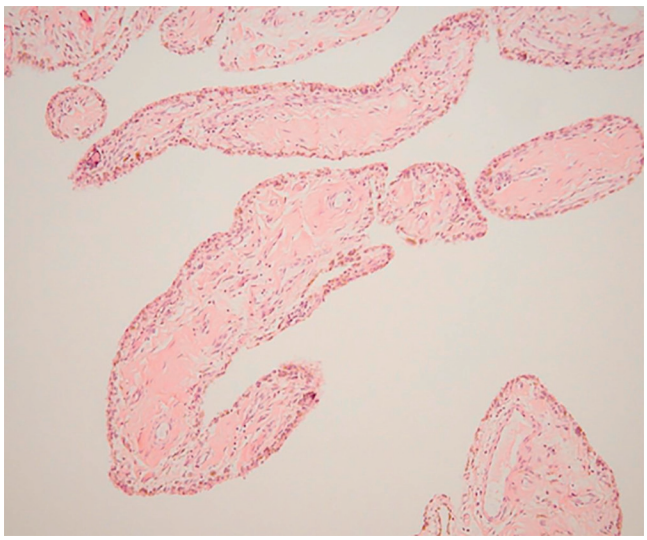

**Figure 119-4** Synovial tissue of hemophilic synovitis of the knee showing fibrous hypertrophy, thickened vascular structures, and iron pigment deposition in superficial synoviocytes and in macrophages in the deeper layers. Hematoxylin–eosin stain, ×1000.

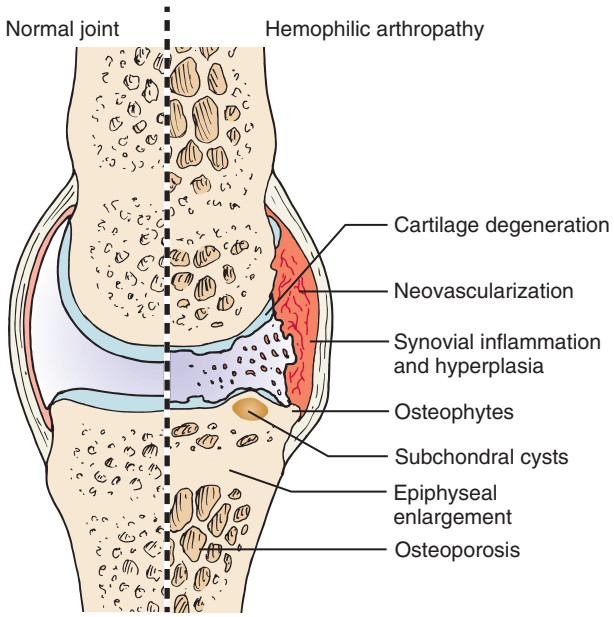

**Figure 119-5** Changes that occur in the synovial joint affected by hemophilic arthropathy.

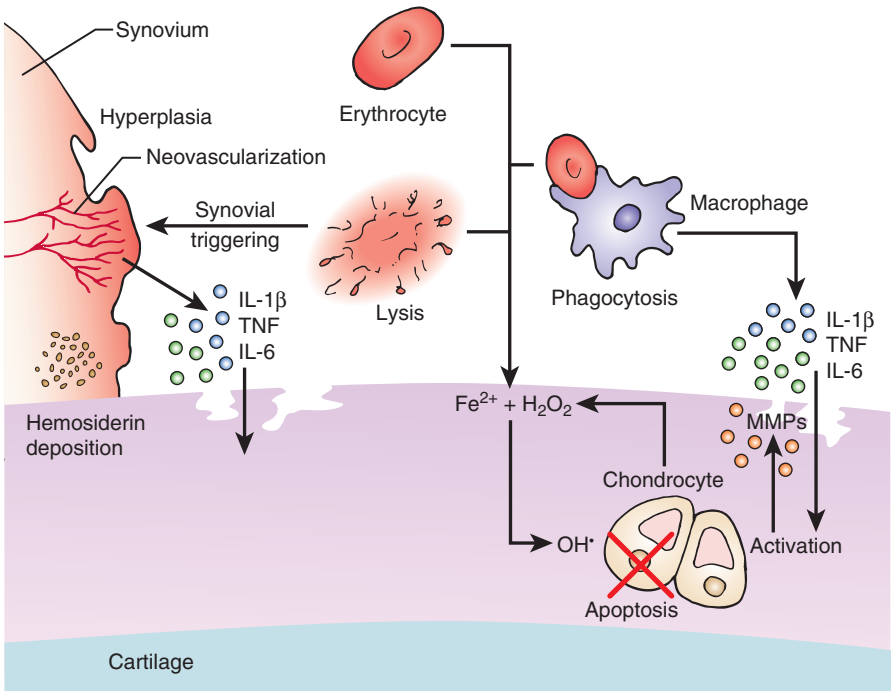

**Figure 119-6** Proposed mechanism of blood-induced joint damage. MMPs, Matrix metalloproteinases.

The normally thin synovial membrane becomes irregular, grossly hypertrophied, villous, friable, and highly vascular.[49,50] Synovial proliferation is postulated to result from an aberrant gene expression induced by the overload of iron.[51] It induces an overexpression of the proto-oncogene *c-Myc*, which is associated with synovial cell proliferation, and of the p53 tumor suppressor binding protein *mdm2*, leading to the abrogation of apoptosis of synovial cells.[52,53] An increased oxygen demand of the hypertrophied synovium causes hypoxia and thus potentially induces the release of growth factors such as vascular-derived endothelial growth factor and the formation of a rich network of brittle capillaries underneath the hypertrophied synovium.[21,54] This process sets up a vicious circle because these fragile vessels are more susceptible to recurrent bleeds. Over time chronic synovitis develops, with pannus invading and eroding marginal cartilage,[55] and ultimately the synovial tissue becomes fibrotic. Clearly there are similarities to the rheumatoid joint.

## Cartilage Degeneration

Cartilage destruction results from both synovial-dependent and synovial-independent processes. Synovial pannus invades cartilage at the periphery of inflamed joints. The inflamed hemosiderotic synovium produces cartilage-destructive pro-inflammatory cytokines and cartilage matrix degrading proteases.[19,50] These destructive properties of synovial tissue on cartilage are already present within 24 to 48 hours after a joint bleed and cause long-lasting damage.[56,57]

Hemarthroses also exert harmful effects directly on the cartilage (see Figure 119-6). Exposure of cartilage explants to whole blood or the combination of erythrocytes and mononuclear cells severely affects cartilage matrix turnover and results in chondrocyte apoptosis.[58,59] The pro-inflammatory mediators IL-1β and TNF produced directly after blood exposure transiently decrease proteoglycan turnover. These cytokines activate chondrocytes to increase $H_2O_2$ production, which in combination with iron derived from erythrocytes, leads to oxidative stress.[60,61] Iron in combination with $H_2O_2$ reacts via the Fenton reaction to form hydroxyl radicals, resulting in chondrocyte apoptosis.[62] Because chondrocytes hardly proliferate and have the responsibility to produce and maintain the extra-cellular matrix, apoptosis of chondrocytes will result in long-lasting impaired matrix turnover. These effects are more pronounced on immature articular cartilage compared with mature cartilage,[63] and impaired cartilage is at least as susceptible to blood-induced joint damage as healthy cartilage.[64] These findings imply that it is important not only to prevent joint bleeds in children but also in patients with already affected joints. These direct effects on cartilage with chondrocyte death represent characteristics of OA.

# TREATMENT OF HEMOPHILIA

Treatment of hemophilia consists of substitution of the deficient clotting factor. This substitution was first performed through whole blood transfusion and the use of fractions from plasma. The introduction of plasma-derived factor concentrates in the 1960s dramatically improved treatment and quality of life in patients with hemophilia. Use of these concentrates enabled prophylactic clotting factor replacement therapy, thereby converting the disease from a severe to a milder form.[65] It reduced the risk of bleeds with the setback of blood-borne infections. The introduction of highly purified, safe concentrates and recombinant products led to a marked reduction in the risk of viral transmissions.

Traditionally, treatment is provided at the time of clinically evident bleeding (known as episodic treatment or on-demand therapy). Nowadays, in developed countries, most patients with severe hemophilia are treated prophylactically, that is, via regular intravenous injection to prevent anticipated bleeding.[1] This treatment is called *primary prophylaxis* because it is initiated before the second clinically evident large joint bleed and before the age of 3 years. With secondary prophylaxis, regular treatment is started after two or more bleeds into large joints, but before the onset of "joint disease" (documented by physical examination and conventional radiography). Prophylactic factor replacement therapy started after the onset of overt "joint disease" is called *tertiary prophylaxis*. The optimum time to initiate prophylaxis, the optimum dosage, the frequency of injection, and whether prophylaxis should be given indefinitely remain unclear.[66-68] Addressing these questions is important because prophylaxis is a highly expensive treatment.

Prophylactic factor VIII replacement typically requires infusions two to three times a week, whereas factor IX can be given less frequently because of a longer half-life. The burden of regular venipunctures in young children is high, and central venous access devices, such as Port-A-Cath and Hickman lines, are often inserted for reliable long-term venous access.[69]

In patients with mild hemophilia A or in hemophilia A carriers, desmopressin, a synthetic analogue of vasopressin, can be administered to release endogenous factor VIII, von Willebrand factor, and tissue plasminogen activator from endothelial storage sites and possibly from platelets.[70] On average a threefold increase in factor VIII levels can be expected, and therefore a residual factor VIII activity of greater than 10% is required. Responsiveness to desmopressin should be tested prior to therapeutic treatment because it varies largely between patients.

Antifibrinolytic therapy is useful to treat or prevent bleeds in areas of increased fibrinolysis, such as skin and mucosal surfaces (epistaxis, menorrhagia, or oral bleeding).[71] It promotes clot stability by inhibiting plasminogen activation in the fibrin clot. Tranexamic acid, the most commonly used antifibrinolytic, acts by reversibly binding to plasminogen and thereby blocking its activation and transformation to plasmin. Epsilon aminocaproic acid is similar to tranexamic acid but is less widely used because it has a shorter half-life, is less potent, and is more toxic.[72]

To improve hemophilia treatment, current research focuses on factor modifications to extend the half-life, along with the development of gene-based therapy.[73,74] Improved bioavailability could be achieved by PEGylation, sialylation, and fusion of the clotting factor to albumin or a fragment of an immunoglobulin. Especially for factor IX, prolongation of the half-life to up to 100 hours could be achieved, allowing substitution intervals of 1 to 2 weeks.

Development of gene therapy is also most promising in hemophilia B because the factor IX gene is considerably smaller than the factor VIII gene, and antifactor VIII immunity is far more frequent. In a trial for hemophilia B, long-term expression of factor IX in levels sufficient to improve the bleeding phenotype has been observed after adeno-associated viral (AAV) vector-mediated gene transfer to the liver.[75] The main concern with this approach is that immune-mediated clearance of AAV-transduces hepatocytes. Moreover, about 40% of men with severe hemophilia B will be excluded from this therapy because of the presence of pre-existing neutralizing antibodies to AAV.[76] Although the initial studies seem promising, a number of significant hurdles have yet to be overcome.

## Complications of Treatment

### Inhibitors

Inhibitors are alloantibodies that neutralize clotting factor activity after infusion of factor VIII or factor IX, these antibodies are primarily of the $IgG_4$ subclass. Risk of inhibitor development is highest in the first period of treatment, especially in the first 50 to 75 exposure days. Patients with severe hemophilia A have a 20% to 30% lifetime risk of inhibitor development, compared with a risk of 5% to 10% in individuals with moderate or mild disease.[77,78] Inhibitors are encountered much less frequently in individuals with hemophilia B, occurring in fewer than 5% of affected individuals.[79] Other risk factors are age and number of exposures to factor, family history of inhibitor development, ethnicity, the causative factor VIII genotype, polymorphisms in the immune system, and intensive factor replacement therapy related to surgery or trauma.[78] Development of factor IX inhibitors is associated with severe allergic or anaphylactic reactions to factor administration; however, these reactions are almost never encountered in patients with hemophilia A.[80] Inhibitor development can be suspected in patients who fail to respond to clotting factor infusion, especially if they were previously responsive. In patients with mild or moderate hemophilia, the presence of an inhibitor can result in conversion of the bleeding phenotype to a more severe form because the inhibitor may neutralize endogenously synthesized clotting factor.

Patients with inhibitors are classified according to the inhibitor titer, expressed in Bethesda units. Patients with titers above five Bethesda units at any time are considered high responders and will show an increase in antibody titer after each exposure to clotting factor. In low responders, antibody titers are below five Bethesda units and do not increase after factor infusion. In these patients, the inhibitor may be transient and replacement therapy may be continued with minimal dose change.

Inhibitor eradication by immune tolerance induction (ITI) through frequent administration of clotting factor is successful in up to 70% of patients with hemophilia A and 30% of patients with hemophilia B.[81,82] ITI in patients with hemophilia B carries the risk of anaphylactic reactions and the development of nephrotic syndrome as a result of complex formation and deposition in the kidney. In patients with hemophilia A who have refractory disease, rituximab may be useful.[83,84] Other immunosuppressive treatments are high-dose prednisolone, cyclophosphamide, or azathioprine.[85]

Control of bleeding in patients with low-titer inhibitors could be achieved through high doses of factor concentrates or in patients with high-titer inhibitors with bypassing agents such as recombinant factor VIIa and (activated) prothrombin complex concentrates.[86,87] These agents act by boosting thrombin generation independently of the presence of factor VIII.

### Viral Infections

The use of non–virus-inactivated plasma, cryoprecipitate, and plasma-derived factor concentrates from multiple human blood donations resulted in high mortality and morbidity as a result of transmission of blood-borne virus infections. More than 90% of patients with hemophilia who were treated with these products before 1985-1987 became infected with hepatitis C.[88-90] A chronic infection developed in the majority of these patients, and in 20% to 30%, it progressed to liver cirrhosis. The cumulative incidence of HIV infection in the United States in the peak years was 78% of the factor VIII recipients and 37% of the factor IX recipients.[91] Other viruses transmitted are hepatitis A, B, or G and cytomegalovirus.

Different measures are taken to ensure safety of plasma-derived factor concentrates, including selection of healthy donors, screening donations for the absence of relevant infectious blood-borne viruses, and screening for viral markers by serologic and nucleic acid testing. Additionally, various viral inactivation procedures are required, such as pasteurization, exposure to solvent-detergent, dry heat, chemical disruption with sodium thiocyanate, or ultrafiltration.[92]

The introduction of recombinant products and the implementation of these measures almost completely eliminated HIV and hepatitis C virus transmission through factor concentrate.[93,94] Hepatitis A and B immunization is still recommended to reduce infection risk, although the risk of infection nowadays is low.[95]

# TREATMENT OF MUSCULOSKELETAL COMPLICATIONS

## Comprehensive Care

Maintaining musculoskeletal health and preventing complications requires encouragement of physical activities to promote physical fitness and normal neuromuscular development. For optimal management of musculoskeletal complications, multidisciplinary care is required. Because prevention is the cornerstone of maintaining musculoskeletal health, the care provided by hemophilia specialists is important to prevent and adequately treat bleeds and provide early recognition of musculoskeletal issues. Physiotherapy is required for recovery after musculoskeletal bleeds and to maintain muscle strength in individuals with established hemophilic arthropathy. A physiatrist can help provide patient education to prevent disabling injuries, care during bleeding episodes, long-term rehabilitation, and orthotics and shoe adaptations.[96] In individuals with end-stage arthropathy, orthopedic surgery is often inevitable.

## Acute Hemarthrosis

The primary aim of therapy for acute hemarthrosis is to stop the bleeding as quickly as possible by administering clotting factor concentrates. The efficacy of joint aspiration along with adequate factor replacement is unclear. Theoretically, shortening the exposure of cartilage to blood might limit blood-induced damage.[97] However, aspiration bears the risk of infection or repeat bleeds, and even when the joint is washed, some blood will always be left in the joint. No data are available on the long-term benefit of aspiration. The most recent in vitro experimental data suggest that limitation of blood exposure to cartilage may prevent tissue damage later.[97] However, these data must be confirmed by clinical studies that will be difficult to perform. Clearly, if the suspicion of infection is high, arthrocentesis is mandatory for diagnosis, but in general it should be avoided. According to the World Federation of Hemophilia guidelines, arthrocentesis may be considered in a bleeding, tense, and painful joint that shows no improvement 24 hours after conservative treatment and after exclusion of inhibitor development.[1] Arthrocentesis should be performed only after appropriate clotting factor replacement and under strictly aseptic conditions. In recurrent or massive bleeds that are unresponsive to appropriate clotting factor replacement, therapeutic embolization could be considered.

Pain relief could be achieved by analgesics, but RICE (rest, ice, compression, elevation) is also commonly recommended to decrease pain, inflammation, and bleeding. Immobilization and avoiding or minimizing weight bearing on the affected joint is important during active bleeding and might be helpful in protecting against cartilage damage.[98] As soon as the swelling and pain subside, active rehabilitation is indicated to minimize muscle atrophy, prevent contractures, and regain functional ability.

## Chronic Synovitis

In chronic synovitis the joint is vulnerable to repeated bleeding, and therefore the goal of treatment is to reduce synovial irritability. This goal might be achieved by (more intensive) prophylactic clotting factor concentrate replacement for 6 to 8 weeks combined with active physiotherapy and cooling. Use of cyclooxygenase (COX)-2 inhibitors may reduce inflammation.[99] Other NSAIDs should be avoided because of the possible impairment of platelet function. If conservative measures fail and chronic synovitis persists with frequent recurrent bleeding, synovectomy might be indicated either surgically, arthroscopically, or through intra-articular injection of radiopharmaceutical agents or chemicals. Radioisotopic synovectomy using a pure beta emitter (yttrium-90 or phosphorus-32) is preferred because it is minimally invasive and requires little factor replacement and less intense rehabilitation afterward. This procedure is very successful in reducing hemarthroses; 60% to 100% are reduced in the majority of patients.[100] If necessary, the procedure can be repeated after 6 months. However, potential direct harmful effects to cartilage in the long term should be taken into consideration.[101] Chemical synovectomy using rifampicin or oxytetracycline chlorhydrate is painful and needs to be repeated weekly until the synovitis is controlled, but it is an appropriate alternative if a radioisotope is not available.[102] Surgical options are preferred in cases in which MRI reveals severe synovial hypertrophy or when bone cysts are present because they carry the risk of dispersing radioactive material outside the intra-articular space. Performing orthopedic surgery in hemophilic patients requires a large supply of clotting factor and intensive rehabilitation.[103]

## Hemophilic Arthropathy

In individuals with established hemophilic arthropathy, the goal of treatment is to improve joint function, relieve pain, and assist with the continuation or resumption of normal activities of daily living. With use of conservative procedures, remarkable benefit can be achieved and surgical interventions can be postponed. For pain relief, adequate analgesic treatment, manual traction of the joint, and in some cases transcutaneous electrical nerve stimulation are indicated.[104] Physiotherapy is crucial for muscle strengthening and stretching, joint stability, and functional training. In patients with involvement of more than one joint, hydrotherapy enables functional training with minimal weight bearing. Orthotics and shoe adaptations provide immobilization, support, stability, compensation for deformities, and reduced weight bearing.[105] In individuals with advanced ankle arthropathy, immobilization with a cast can provide insight about whether arthrodesis would be helpful.

In individuals with end-stage arthropathy, orthopedic surgery is often indicated. Different surgical options could be considered depending on the joint or specific condition requiring correction. Joint replacement therapy of the knee and hip and less commonly of the elbow and shoulder and ankle arthrodesis are the most performed procedures. Joint replacement therapy is very successful in relieving pain and increasing functional activities and participation. Hip replacement usually improves ROM, whereas after knee replacement therapy, a restricted ROM may limit functional recovery.[106] Ankle arthrodesis is very effective in diminishing pain and stopping recurrent joint bleeding. Drawbacks of arthrodesis are the loss of mobility of the joint and the possibility of overloading other joints of the lower limb/foot, necessitating surgical repair of other joints.[107,108] Total ankle replacement has the advantage of preserving motion, but long-term follow-up data are scarce. Higher rates of aseptic loosening and deep infections due to poor bone quality and increased risk of micro-bleeds at the prosthesis-bone interface are concerns.[109,110] In this respect, a new surgical approach for the ankle could be joint distraction. Joint distraction in the treatment of OA has gained increasing attention in recent years.[111] This technique also seems very helpful for treatment of hemophilic ankle arthropathy,[112] although larger and prospective studies are needed.

Other procedures performed in end-stage arthropathy or in case of severe contractures include soft tissue contracture release, arthroscopic débridement for intra-articular adhesions and impingement, tendon reconstruction, osteotomy to correct angular deformity, and radial head excision combined with synovectomy if enlargement and erosion of the radial head cause mechanical blockage of forearm rotation.

Major orthopedic procedures can be performed safely and successfully, even in patients with inhibitors.[113] Surgical interventions should always be performed at or in

consultation with a comprehensive hemophilia treatment center.[114] Adequate quantities of clotting factor concentrates should be available, as well as blood bank support and laboratory facilities for reliable monitoring of clotting factor level and inhibitor testing. In patients who have arthropathy of more than one joint of the lower extremities, multiple procedures could be combined during one in-hospital stay, either in a single session or staged.[115] With this approach, reduced quantities of clotting factor concentrate are required and a faster rehabilitation is expected. Careful assessment by a multidisciplinary team is a prerequisite to ensure that recovery will not be compromised for any of the procedures.

## CONCLUSION

Despite the use of prophylactic infusions of clotting factor starting at an early age, it is not possible to completely prevent hemarthroses and the consequent joint damage. Patients with severe hemophilia who receive intermediate dose prophylaxis still experience 0.8 to 2.7 joint bleeds per year.[116] Patients at risk of the development of joint damage are those who do not have access to clotting factor treatment, experience the development of inhibitors, are not compliant with their prophylactic clotting factor treatment, have unrecognized and thus untreated joint bleeds, have post-traumatic bleeds, and receive on-demand therapy. Diagnostic strategies are needed to detect early changes within a joint and to evaluate joint damage progression regularly; biochemical markers of joint tissue damage are very promising in this respect.

Gene therapy to "cure" hemophilia faces many challenges regarding efficacy and safety. Specific therapies opposing inflammatory cytokines[117,118] or reducing synovial iron deposition[119] to limit synovitis and cartilage damage and procedures aiming at cartilage restoration[112,120] in overt joint damage may become plausible new approaches, although introduction of these therapeutic strategies into clinical practice remains challenging. In the meantime, emphasis should be placed on preventing hemarthrosis by clotting factor replacement, education, adequate pain relief, physical therapy, and maintaining physical activity to reduce development of end-stage arthropathy.

CHAPTER 120

# Rheumatic Manifestations of Hemoglobinopathies

Carlos J. Lozada • Elaine C. Tozman

**KEY POINTS**

- Hemoglobinopathies are inherited diseases caused by mutations in globin genes.
- Thalassemias are inherited defects in globin chain synthesis resulting in hypochromia and microcytosis.
- Skeletal changes in thalassemias can result in cortical thinning, osteoporosis, and vertebral compression fractures.
- Sickle cell disease is a single gene disorder caused by homozygous inheritance for sickle cell hemoglobin.
- Vaso-occlusive crises of bone occur in people with sickle cell disease and result in severe pain at the site of bony infarction, typically of long bones.
- The index of suspicion for septic arthritis should be high in patients with sickle cell disease who present with fever and joint pain.
- Hyperuricemia can be seen in people with sickle cell disease and thalassemias, but gout is uncommon.

Hemoglobin (Hb) has a tetrameric structure consisting of two pairs of α-globin and two non–α-globin polypeptide chains, each associated with a heme group. The interaction of these chains is responsible for the quaternary structure of the Hb molecule and its normal function. The fundamental role of Hb is oxygen transport.

Hemoglobinopathies are inherited diseases caused by mutations in globin genes. Abnormalities in Hb can alter red blood cell shape, deformability, and viscosity. Approximately 1000 mutations have been described[1]; however, most are *not* associated with clinical disease. The gene mutations that result in sickle cell disease and thalassemia syndromes cause diseases that often involve the musculoskeletal system and will be discussed in this chapter.

## THALASSEMIAS

The term *thalassemia* is derived from a Greek term that roughly means "the sea" (Mediterranean) in the blood and was used to describe anemias in people from Italy and Greece. The term is now used to refer to inherited defects in globin chain biosynthesis.[2] Individual syndromes are named according to the globin chain whose synthesis is adversely affected. For example, α-globin chains are absent or reduced in patients with α-thalassemia; β-globin chains are absent or reduced in patients with β-thalassemia; δ- and β-globin chains are absent or reduced in patients with δβ-thalassemia; and so on. Thalassemias are inherited as pathologic alleles of one or more of the globin genes located on chromosomes 11 and 16 and range from total deletion or rearrangement of the loci to point mutations that impair transcription, processing, or translation of globin messenger RNA.

As a consequence of reduced globin chain production, a reduction of functioning Hb tetramers occurs. Hypochromia and microcytosis are found in all patients with thalassemia. In the milder forms of the disease, these changes may be barely detectable. Impaired globin synthesis leads to an imbalance of the individual α- and β-subunits. Free or "unpaired" α-, β-, and γ-globin chains are either highly insoluble or form homotetramers (Hb H and Hb Bart's) that cannot release oxygen normally or are relatively unstable and precipitate as the cell ages. Excess α-globin chains, for example, continue to accumulate and precipitate in individuals with β-thalassemia. Unpaired subunits are the major sources of morbidity and mortality (Tables 120-1 and 120-2).

Thalassemias have been encountered in virtually every ethnic group and geographic location, but they are most common in the Mediterranean basin and tropical or subtropical regions of Asia and Africa. The "thalassemia belt" extends from the Mediterranean across the Arabian Peninsula and through Turkey, Iran, and India to southeastern Asia and southern China. The prevalence of thalassemia in these regions ranges from 2.5% to 15%. As with sickle cell anemia, thalassemia is most common in areas affected by endemic malaria. Malaria infection in thalassemia heterozygotes results in milder disease and confers a selective advantage on reproductive fitness. The gene frequency of thalassemia has become fixed and is high in populations exposed to malaria over many centuries.

## SICKLE CELL ANEMIA AND RELATED DISORDERS

Sickle cell anemia is a single gene disorder caused by homozygous inheritance for sickle Hb (Hb S). Hb S is identical to normal Hb (Hb A) except for the replacement of glutamic acid, the sixth amino acid in β-globin, with valine. Hb S is capable of carrying oxygen, but once the oxygen is released, the Hb joins with other Hb S molecules to form rigid rods that bend the normally flexible, disk-shaped red blood cells into distorted narrow crescents. The sickled cells impede blood flow when they stick to the walls of blood vessels and to other blood cells. About 10% of black Americans are heterozygotes—that is, they inherit a sickle globin

**TABLE 120-1** α-Thalassemias

| No. of Missing α Genes | | Clinical Presentation |
|---|---|---|
| 1 | Silent carrier | No overt manifestations |
| 2 | Thalassemia trait | Hypochromic, microcytic with mild anemia |
| 3 | Hemoglobin H disease | Hypochromic, microcytic with hemolytic anemia, hepatosplenomegaly, and jaundice |

gene from one parent and a normal gene from the other parent and have sickle cell trait. They have no significant clinical problems unless they are subjected to marked dehydration or hypoxia.[3] Rarely these individuals experience splenic infarction, stroke, or sudden death after strenuous physical activity, particularly at a high altitude. Individuals with sickle cell trait may have impaired ability to form concentrated urine (hyposthenuria), and a few have episodes of painless hematuria as a result of medullary infarction. Other internal organ damage is extremely uncommon, and heterozygotes have a normal life expectancy.

One-fourth of the children of parents with sickle trait will be homozygotes and have red blood cells containing primarily Hb S and no Hb A. These individuals have severe hemolytic anemia and episodes of vaso-occlusion that cause acute bouts of pain and progressive organ damage. A similar clinical phenotype is encountered in individuals who are compound heterozygotes—that is, those who inherit the sickle gene from one parent and, from the other parent, either a β-thalassemia gene or a gene that encodes Hb C, another β-globin structural mutant. Patients with $S/\beta^0$ thalassemia[1] are unable to make any Hb A and are as severely affected as those with Hb SS disease. In contrast, patients with Hb $S/\beta^+$-thalassemia or with Hb SC disease have less morbidity and a longer life span.

The hallmark of sickle cell disease is the vaso-occlusive pain crisis,[4] which is the most common clinical manifestation but can occur with varying frequency in different individuals. It results from the complex interplay between sickled red blood cells, neutrophils, endothelium, and plasma factors. The result is tissue hypoxia, leading to tissue death and associated pain. Episodes may be precipitated by dehydration, infection, and cold weather, although in half of the cases, no precipitating factor is found. Repeated splenic infarctions in childhood result in "autosplenectomy" and loss of splenic function by age 6 to 8 years in approximately one-half of patients.[5]

## DIAGNOSIS OF HEMOGLOBINOPATHIES

One in 12 African-Americans has sickle-cell trait, one in 40 carries Hb C, and one in 40 carries the trait for β-thalassemia.[6] Latin Americans are an underappreciated population affected by sickle cell disease.[7] For example, it is estimated that 30,000 people in Brazil have sickle cell disease. African and African-American patients are at increased risk of carrying Hb S and other hemoglobinopathies and should be offered preconception or prenatal screening. Hb S is also more common among individuals of Mediterranean, Middle Eastern, and Asian Indian descent. The American College of Obstetricians and Gynecologists recommends that patients at risk for having a child with hemoglobinopathy be offered prenatal genetic counseling and a variety of tests to document the Hb abnormality.[8] In the United Kingdom, the Royal College of Obstetricians and Gynaecologists provides clinical guidelines for the management of sickle cell disease in pregnancy and standards of care from both hematology and the sickle cell community.[9] Prenatal diagnosis can be performed with either chorionic villus sampling or amniocentesis.

Because detection of α-thalassemia or α-thalassemia trait is based on molecular genetic testing and is not detectable using Hb electrophoresis, routine carrier screening is not offered. If microcytic anemia is present in the absence of iron deficiency and the Hb electrophoresis is normal, then testing for α-thalassemia should be considered, particularly among individuals of Southeast Asian descent. Sickle cell anemia can be accurately diagnosed with high-performance liquid chromatography and isoelectric focusing. Rapid methods such as solubility testing and sickling of red blood cells using sodium metabisulfite are less reliable tests. These tests are suitable for large field studies because they require only a drop of blood and use stable reagents, but they do not distinguish between homozygotes and heterozygotes. Newborn screening is mandatory in most of the United States and is well established, although not mandatory, for both sickle cell disease and thalassemias in the United Kingdom. Such screening tests vary in other areas of the world and may not be performed.[7] Polymerase chain reaction is the method of choice for prenatal diagnosis.

## TREATMENT

Hydroxycarbamide (hydroxyurea) is the only drug approved by the U.S. Food and Drug Administration to treat sickle cell disease. It can reduce the number of painful episodes and hospitalizations, but only about two-thirds of adult patients have a response to this drug.[10]

Bone-marrow transplants can provide a cure because they replace the faulty hematopoietic stem cells that produce sickle cells with ones that make healthy red blood cells.[11]

However, transplants are expensive, not widely available, and have associated risks such as infections and life-threatening immune-system reactions.

Gene therapy is another potentially successful treatment for sickle cell disease.[12] Conventional gene therapy, also known as gene addition, typically involves inserting new genes. Usually, a harmless virus is modified with the gene to be inserted, and this "viral vector" is mixed with cells from the patient in vitro. The virus searches out the cells and inserts the gene into the cells' DNA, after which the cells are transplanted into the patient. Gene editing is more specific when the faulty DNA sequence is removed and a piece of laboratory-created DNA is inserted. In both approaches, the modified DNA dictates the formation of a normal, working protein. A team led by Alan Flake at the Children's Center for Fetal Research at the Children's Hospital of Philadelphia has successfully treated sickle-cell disease in utero in mice and dogs, and trials in monkeys are under way.[13] Stem cells from the mother are collected and injected into the bloodstream of the fetus. No destruction of the fetal immune system is required, because the fetal and maternal immune systems are naturally tolerant of one another.

## MUSCULOSKELETAL INVOLVEMENT: SICKLE CELL DISEASE

### Vaso-Occlusive Crisis of Bone

Bone involvement in patients with sickle cell disease is the most common clinical manifestation of the disease, both as an acute process and as a chronic symptom[14] (Table 120-3). Painful osteoarticular crisis was the most common reason for emergency care of children with sickle cell disease in an African population (58.6%).[15] All patients experience painful vaso-occlusive crises, which usually begin in late infancy and continue throughout life. Patients typically report pain in the chest, low back, and extremities. Abdominal pain may mimic acute abdomen of other causes. Fever is often present, even in the absence of infection. Although microvascular occlusion can occur in any organ, it is common in tissues with low blood flow, such as the bone marrow, where deoxygenation and polymerization of Hb S leads to bone thrombosis, infarction, and necrosis. Spinal cord infarction can occur.[16] The medullary cavity or the epiphysis of the bone is affected. Patients have severe pain in one or more areas of their bones, with tenderness, erythema, and swelling of the infarcted bone. Generalized symptoms of fever and leukocytosis occur, and most patients recover without sequelae (Figure 120-1).

When infarction involves the vertebral body, collapse and a fish mouth deformity can result.[17] Bone infarctions can occur in any bone, with a predilection for long bones. The most common sites are the tibia/fibula (30%), the femur (25%), and the radius, ulna, and humerus (21%).[18] MRI is sensitive in detecting bone and bone marrow infarction, but this technology is not useful in distinguishing acute infarction from osteomyelitis.[19]

**TABLE 120-3** Bone and Joint Involvement in Sickle Cell Disease

| Diffuse chondrolytic arthritis |
| Gouty arthritis |

### Dactylitis

In young children, in the range of 1 to 2 years of age and younger than 7 years, vaso-occlusion manifests in the bone marrow of the small bones of the hands and feet and dactylitis occurs.[20] Dactylitis is also called hand-foot syndrome. Patients have painful swellings of one or more digits (Figure 120-2) as extensive infarction of the marrow, medullary trabeculae, and inner layer of cortical bone occur.

**Figure 120-1** Bony infarcts in the femur of a patient with sickle cell disease. *(From The Radiology Assistant.)*

**Figure 120-2** Hand of a child with sickle cell disease. *(Courtesy Larry B. Mellick. From https://www.youtube.com/watch?v=AChPlzPEA7Y.)*

Subperiosteal new bone formation follows, and as the episode resolves within 2 weeks, radiographs show a "moth-eaten" appearance of the involved digits (Figure 120-3). Rarely, involvement of the epiphysis causes premature fusion and shortened digits.

## Osteomyelitis

Patients with sickle cell disease have an increased risk of infections, including osteomyelitis,[21] particularly from encapsulated organisms that are presumably secondary to loss of functional splenic tissue. The most common cause of osteomyelitis is *Salmonella*, followed by *Staphylococcus aureus* and Gram-negative enteric bacteria.[22] One proposed explanation for the frequency of bowel organism–derived infections has been intravascular sickling leading to bowel microinfarctions.[23] Diagnosis of osteomyelitis in the context of sickle cell disease is an important management issue because the clinical symptoms of pain, swelling, tenderness, and fever are similar to those of bone vaso-occlusive crisis. Elevated markers of inflammation occur in both conditions. No single laboratory test or imaging modality reliably differentiates osteomyelitis from infarction. Until a definite diagnosis can be made, treatment with anti-microbial therapy should be provided.[24]

## Acute Synovitis and Septic Arthritis

When the epiphysis is involved by infarction of sickle cell crisis, a joint effusion may develop. This presentation is an acute synovitis and is clinically indistinguishable from a septic joint.[25] Synovial fluid should be examined and cultured for accurate diagnosis. In a retrospective review of 2000 consecutive adult patients with sickle cell disease, 3% had septic arthritis.[26] The majority of these patients (56/59) had Hb SS. Thirty-six of the 59 infections involved the hip. Symptoms were pain, swelling, and fever higher than 38.2° C, a peripheral white blood cell count of 15,000/mm$^3$, erythrocyte sedimentation rate greater than 24 mm/hour, and C-reactive protein greater than 20 mg/L. Cultures were positive in 96% of the joint aspirates, with staphylococcus and Gram-negative infections the most common. Prior diagnosis of osteonecrosis, osteomyelitis, and comorbid medical conditions of diabetes mellitus and use of corticosteroids and hydroxyurea were associated with septic arthritis. It is suggested that a clinician should have a high index of suspicion for septic arthritis in patients with sickle cell disease who present with fever and joint pain. Distant osteomyelitis was more often the source of a joint infection than contiguous osteomyelitis. If a joint infection is suspected, the patient should undergo aspiration and culture of the synovial fluid.

**Figure 120-3** Radiograph of the hand of a child with sickle cell disease. *(From Medscape. Available at http://img.medscape.com/pi/emed/ckb/radiology/336139-413542-8885tn.jpg.)*

Another form of arthritis in patients with sickle cell disease is polyarticular (80%) and symmetric (60%) in the majority of patients and generally involves the large joints of the lower extremity.[27] Symptoms last less than 1 week, and radiographic changes are consistent with periarticular osteopenia, erosions of bone, and joint space narrowing.

## Growth Disturbance

A majority of children with SS disease will show decline in growth compared with normal peers.[28] Puberty is delayed on average by 12 to 24 months, as is skeletal age. Factors such as nutritional status and inactivity could be modified and decrease the effect on growth. Delayed skeletal maturation in children also can occur.[29]

## Osteopenia and Osteoporosis

Osteopenia and osteoporosis are prevalent in Hb SS disease, especially given the young age of the patients. The lumbar spine appears to be the site most often affected. Low body

mass index is a consistent correlate of decreased bone density, as are low vitamin D levels.[30]

### Osteonecrosis

Vaso-occlusion resulting in infarction of articular surfaces of long bone occurs most commonly in the femur, followed by the humerus.[31] It was previously thought to occur with increased frequency in Hb SC disease as opposed to Hb SS disease. However, because of the increased longevity of patients with Hb SS disease, its prevalence is greatest in patients with Hb SS disease.[32] By age 33 years, 50% of patients will have avascular necrosis of the femoral head. The presence of concurrent deletional α-thalassemia and a history of frequent vaso-occlusive crises are classic risk factors for femoral avascular necrosis. Patients present with chronic joint pain with progressive decrease in range of motion of affected joints. Multiple joints are commonly involved. The vast majority of untreated patients with avascular necrosis will progress to femoral head collapse within 5 years.

Symptoms always preceded hip collapse. The duration to collapse was shorter with more advanced stages at study onset, and the majority of patients progress to symptomatic avascular necrosis that requires intervention.[33]

Avascular necrosis has been treated with a number of modalities including core decompression, osteotomy, bone grafting, surface arthroplasty, and joint replacement.[34] The only randomized trial in avascular necrosis compared core decompression and physical therapy versus physical therapy alone and did not show a difference in outcome between the two arms; however, follow-up was short, and a significant number of stage III hips were included. Core decompression is a useful option in early stage avascular necrosis. Several studies associate total hip replacement in individuals with sickle cell disease with a higher rate of orthopedic and medical complications.[35,36] However, other studies show a lower rate of orthopedic complications.[37] Structural bone diseases in people with sickle cell disease make joint replacement technically challenging (see Chapter 103).

### Iron Metabolism

Red blood cell transfusions are a mainstay in the treatment of both acute and chronic sickle cell disease complications.[38] Most patients receive at least one transfusion in their lifetime, usually for acute complications. Blood transfusions increase arterial oxygen pressure and Hb oxygen affinity, thereby reducing red blood cell sickling, and they also improve microvascular perfusion. Furthermore, regular blood transfusion regimens suppress endogenous erythropoiesis and therefore the production of red blood cells containing sickle Hb. Iron metabolism and consequently patterns of iron loading differ in sickle cell disease and thalassemia.[39]

Erythropoiesis is variably increased in sickle cell disease, but it is not ineffective. Unlike patients with thalassemia, patients with nontransfused sickle cell disease do not develop systemic iron overload because of increased iron absorption, and they may actually present with iron deficiency, possibly related to intravascular hemolysis and the resulting excessive urinary loss of iron. Inflammation, which is part of the pathophysiology of sickle cell disease, increases synthesis of hepcidin and consequently decreases iron absorption and enhances retention of iron within the reticuloendothelial system. As a result, tissues and organs affected by iron overload are different in sickle cell disease and thalassemia. Iron-induced cardiac and endocrine dysfunction is less common in sickle cell disease. Musculoskeletal manifestations of iron overload include a symmetrical, polyarticular arthropathy with bony enlargement and minimal inflammation that can develop in 25% to 50% of patients. It notably affects the second and third metacarpophalangeal joints but also the proximal interphalangeal joints, wrists, elbows, shoulders, and hips. Osteoporosis can affect up to 25% of patients.

## MUSCULOSKELETAL INVOLVEMENT: THALASSEMIAS

### Decreased Bone Density, Osteoporosis

Skeletal changes in people with untreated thalassemia are related to bone marrow hyperplasia, resorption of cortex, rarefaction of cancellous bone with coarsening of the trabeculae, and a generalized decrease in bone density.[40] In patients with thalassemia major, onset of the radiographic changes can be seen in their first year of life. Involvement of the spine, skull and facial bones, ribs, and metaphyses of long bones are typical (Figure 120-4).

In the spine, osteoporosis and cortical thinning are associated with vertebral compression fractures (Table 120-4). After an initial increase in the height-to-width ratio of the vertebral body, thinning of the subchondral bone plates occurs and the bones become biconcave and wedge shaped as multiple compression fractures occur. Patients can experience scoliosis and kyphosis.[41] Lateral plain radiographs of the spine may show a "bone-within-a-bone" appearance as the end plate depression is evident (Figure 120-5). MRI studies show predominance of red marrow in the vertebrae and early degeneration of the intervertebral disks of the lower thoracic and lumbar spine.[42] Abnormal intravertebral iron deposition also can be seen.

### Extramedullary Hematopoiesis

Extramedullary hematopoiesis is seen as extraosseous extension of red marrow with symmetrical lobulated confluent masses expanding in the paravertebral and presacral spaces. These soft tissue masses have intermediate T1 signal, variable intensity of T2-weighted sequences, and mild gadolinium enhancement. Radionuclide imaging with

technetium-labeled sulfur colloid may help define the hematopoetic nature of the masses.[43] Spinal cord compression occasionally occurs as a result of epidural marrow extension. In the skull, marrow expansion causes widening with thinning of the outer table and thickening of the inner table, with remodeling of the skull (tower skull; Figure 120-6).

## Iron Metabolism

The anemia of thalassemia major becomes symptomatic between 6 months and 2 years of age, requiring the institution of a regular transfusion program. As a consequence of continuous anemia, erythropoiesis, although inefficient, can be intense; the bone marrow undergoes an enormous expansion with consequent distortion of facial features, and the plasma volume increases. In addition, hepatosplenomegaly develops. A regimen maintaining a minimum Hb concentration of 9.5 to 10.5 g/dL prevents all the aforementioned complications and fosters normal growth at least until puberty. Transfusion therapy results in iron overload in various tissues, and iron chelation therapy prevents accumulation of iron, promotes normal growth, and prevents death.[44] Deferoxamine chelation is effective but challenging to use because of its cost and the inconvenience of prolonged subcutaneous infusions. Deferiprone, an oral iron chelator, has improved compliance and access to iron chelation therapy. However, serious complications can occur when it is used, including agranulocytosis. Mild arthralgias and/or arthritis may occur in up to 38% of patients[45] and usually resolve on their own or with NSAIDs. In some patients, however, severe arthropathy related to deferiprone develops, requiring discontinuation of iron chelation therapy. In addition, erosive epiphyseal, physeal, and

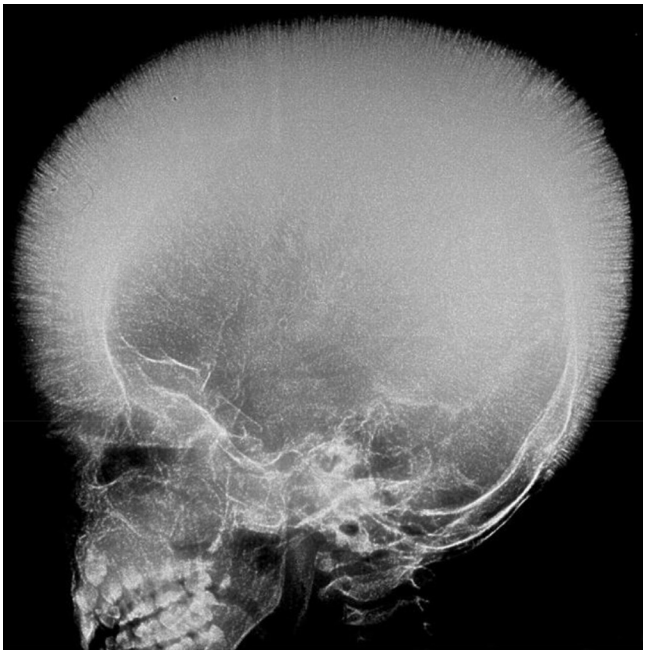

**Figure 120-6** Skull of a child with thalassemia. *(From Azam M, Bhatti N: Hair-on-end appearance. Arch Dis Child 91:735, 2006.)*

metaphyseal changes are seen on radiographs of the long bones of the hands of symptomatic children.[46]

## COMORBID RHEUMATIC DISEASE

### Autoimmune Disorders

The occurrence of systemic autoimmune diseases, including rheumatoid arthritis and systemic lupus erythematosus, has occasionally been reported in patients with hemoglobinopathies.[47] Some authors have suggested that their association has an increased risk.[48] Several cases of mild recurrent arthritis have been reported in patients with thalassemia. Rheumatoid arthritis has rarely been described in patients with sickle cell disease.[49] The prevalence and clinical features of rheumatoid arthritis in patients with thalassemia is unknown. A review of medical records of patients with either thalassemia or sickle cell disease followed up over a decade in Greece provides insight.[50] Rheumatoid factor was detected in 23% of 90 patients, and anti-citrullinated protein antibodies were detected in only 2%. A low titer of positive anti-nuclear antibody (ANA) was present in nearly half of patients, and double-stranded DNA antibodies were found in one patient. Four percent of the patients with thalassemia major fulfilled American College of Rheumatology criteria for rheumatoid arthritis and received low-dose corticosteroids to control synovitis. One patient underwent methotrexate therapy. Patients with rheumatoid arthritis had no specific features that distinguished them from the other patients with hematologic disease. The nature of the rheumatoid arthritis was mild, and extra-articular features were uncommon.

Abnormalities of the immune system can occur in patients with sickle cell disease. Immune deficiency and the presence of autoantibodies have been described in frequencies higher than that of control groups of Africans and Caucasians, and up to 20% of patients are positive for ANAs.[51] The presence of these autoantibodies could be related to genetic factors and/or environmental influences. Although it has been suggested that a deficiency of the alternative complement pathway in patients with sickle cell disease was a predisposing factor in the development of immune complex diseases, this mechanism has not been confirmed.[52]

Autoimmune disease in adults with sickle cell disease may fail to be diagnosed or diagnosis may be delayed as a result of shared clinical manifestations. Bone and joint, lung, cardiac, renal, and central nervous systems may be involved in either autoimmune disease or sickle cell disease. Recognition of an autoimmune disease in patients with sickle cell disease may require a change in therapy, and the use of immunosuppressive medications may result in exacerbation of sickle cell disease.[53]

### Gout

Hyperuricemia and gout are uncommon in people with primary red blood cell disorders but have been reported in patients with sickle cell disease, Hb SC and CC disease, and thalassemias.[54] Increased red blood cell turnover in sickle cell disease can lead to hyperuricemia, as can renal tubular involvement and a decrease in uric acid excretion. Two patients with tophaceous gout and sickle cell disease have been reported.[55] Appropriate therapy is treatment of the underlying hematologic disease and typical measures for acute gout. In studies from the 1970s, hyperuricemia was reported as a common feature of sickle cell disease, occurring in up to 41% of patients.[56] To assess the recent prevalence of hyperuricemia and gout in adult patients with sickle cell disease, 65 consecutive patients with sickle cell disease in one center in France were studied during a 2-year period.[57] Hyperuricemia was observed in only 9.2% of the patients in the cohort, and none had gout.

## CONCLUSION

Hemoglobinopathies, particularly sickle cell disease and the thalassemias, are often associated with significant and varied musculoskeletal manifestations, including osteonecrosis, arthropathies, and vertebral fractures. Awareness of the clinical presentations associated with these manifestations is essential so they are recognized by the physician and an effective management strategy can be formulated.

CHAPTER 121

# $IgG_4$-Related Disease

John H. Stone • Shiv Pillai

**KEY POINTS**

- **Immunoglobulin $G_4$-related disease ($IgG_4$-RD) is an immune-mediated condition capable of affecting essentially any organ. The most commonly affected tissues are the major salivary glands, pancreas, orbits, lymph nodes, and retroperitoneum.**
- **Most patients have elevated serum $IgG_4$ concentrations, often to extremely high levels, but a significant number of patients have normal serum $IgG_4$ levels.**
- **The hallmark pathologic features of $IgG_4$-RD are a lymphoplasmacytic infiltrate with a high percentage of plasma cells staining for $IgG_4$, storiform fibrosis, obliterative phlebitis, and mild to moderate tissue eosinophilia. The foundation of the diagnosis rests upon robust clinicopathologic correlation.**
- **The peripheral blood of patients is characterized by high numbers of plasmablasts, regardless of whether the serum $IgG_4$ concentration is elevated. These cells appear to correlate with disease activity.**
- **Nearly all patients respond well to glucocorticoids, but most patients ultimately require long-term maintenance therapy or intermittent retreatment.**
- **B cell depletion strategies appear to be effective, perhaps in part through their interference with the presentation of antigen by B cells to T cells; the importance of this pathway is becoming more clear in disease pathophysiology.**

$IgG_4$-related disease ($IgG_4$-RD) is a multiorgan immune-mediated condition that mimics many malignant, infectious, and inflammatory disorders.[1-4] The diagnosis links numerous conditions once regarded as isolated, single-organ diseases that existed outside of any known underlying systemic condition (Table 121-1). $IgG_4$-RD has many similarities to sarcoidosis and certain forms of systemic vasculitis. These diseases are all protean conditions in which the histopathologic findings are consistent across a wide range of organ systems.

Awareness of $IgG_4$-RD is essential because it generally responds well to treatment. Moreover, the approaches to the treatment of $IgG_4$-RD differ significantly from those of its mimics. Regardless of the organ affected, $IgG_4$-RD has a tendency to form mass lesions and therefore is often confused with cancer. In addition, autoimmune disorders such as Sjögren's syndrome, granulomatosis with polyangiitis, and idiopathic membranous nephropathy can also be difficult to distinguish from $IgG_4$-RD. Understanding the immune dysregulation associated with $IgG_4$-RD will likely provide important insights into the processes of fibrosis, B and T lymphocyte cross-talk, and processes central to the pathophysiology of other conditions.

## EPIDEMIOLOGY

Mapping the epidemiology of $IgG_4$-RD has been hampered by insufficient awareness of this relatively newly recognized disease. The disease first crept into the medical literature in 2003.[5,6] Definitive diagnosis generally requires a biopsy, insightful interpretation of the pathologic features, and rigorous clinicopathologic correlation. $IgG_4$-RD was recognized first in the pancreas, and although the overall prevalence of type 1 ($IgG_4$-related) autoimmune pancreatitis (AIP) was estimated to be 2.2 cases per 100,000 population in Japan,[7] this figure certainly underestimates the true prevalence of AIP because the study was conducted only shortly after the appearance of the first publications about the disease.

Moreover, the pancreas is only one of more than a dozen organs affected by $IgG_4$-RD. Among the different organs affected, AIP, sialadenitis (particularly of the submandibular gland [Figure 121-1]), a variety of orbital and periorbital lesions (e.g., dacryoadenitis), lymphadenopathy, and $IgG_4$-related retroperitoneal fibrosis (RPF) (Figure 121-2) are among the most common disease features. A variety of lesions in the lung (Figure 121-3), kidney (Figure 121-4), and aorta (Figure 121-5) are also well described.

The typical patient with $IgG_4$-RD is a middle-aged to elderly man.[7,8] In individuals with AIP, the mean age at diagnosis 67 years and the male : female ratio is 3 : 1.[7] When all types of $IgG_4$-RD organ involvement are considered, however, this ratio may be closer to 3 : 2.[9] The male predilection contrasts with the classic autoimmune diseases but does not appear to affect disease severity; when women are afflicted by $IgG_4$-RD, the disease severity is generally no less than the phenotype in men.[9] HLA associations and other potential genetic links of $IgG_4$-RD remain incompletely characterized. Detailed genetic studies have not yet been undertaken in populations of sufficient size, but familial cases appear to be very rare. Features of the epidemiology of $IgG_4$-RD will remain elusive until the disease is recognized more broadly.

## ETIOLOGY AND PATHOGENESIS

Most features of the current understanding of the pathophysiology of $IgG_4$-RD remain highly theoretical, but the field is changing quickly. The theory that $IgG_4$ itself is a

crucial player in cause of disease, which held sway for many years after the first recognition of the elevated serum $IgG_4$ concentrations in "sclerosing pancreatitis," is swiftly falling away. Figure 121-6 outlines current thinking regarding many of the different pathways contributing to the disease.

## The $IgG_4$ Molecule: Central or Not?

Many patients with $IgG_4$-RD have striking and disproportionate elevations of serum $IgG_4$ concentrations. In addition, except for advanced cases characterized primarily by fibrotic lesions, $IgG_4^+$ plasma cells are nearly always present in abundance at sites of disease. Substantial elevations of plasmablasts have also been reported in $IgG_4$-RD, and these cells appear to mirror disease activity.[10,11] Consequently, the $IgG_4$ antibody and humoral immunity have been emphasized most prominently in discussions of pathophysiology thus far.

$IgG_4$ itself is unlikely to drive the pathogenesis of $IgG_4$-RD. The subclasses of IgG differ from each other in important ways, defined by the sequences of their heavy chain constant domains. $IgG_4$, normally the least abundant of all of the subclasses, accounts for approximately 4% of the total immunoglobulins among healthy individuals. The $IgG_4$ molecule has unique chemical properties that render it unlikely to play a central inflammatory role. $IgG_4$ demonstrates weak binding to C1q and to Fc-γ receptors because of a critical few amino acid differences in its CH2 domain.[12,13] As a result, the ability of $IgG_4$ to activate the classic

**TABLE 121-1** Previously Recognized Conditions that Are Part of the $IgG_4$-Related Disease Spectrum

| |
|---|
| Mikulicz's disease (affecting the salivary and lacrimal glands) |
| Küttner's tumor (affecting the submandibular glands) |
| Riedel's thyroiditis |
| Eosinophilic angiocentric fibrosis (affecting the orbits and upper respiratory tract) |
| Lymphomatoid granulomatosis, grade 1 (commonly affecting the lungs) |
| Multifocal fibrosclerosis (commonly affecting the orbits, thyroid gland, retroperitoneum, mediastinum, and other tissues/organs) |
| Lymphoplasmacytic sclerosing pancreatitis/autoimmune pancreatitis |
| Inflammatory pseudotumor (affecting the orbits, lungs, kidneys, and other organs) |
| Mediastinal fibrosis |
| Retroperitoneal fibrosis |
| Sclerosing mesenteritis |
| Periaortitis/periarteritis |
| Inflammatory aortic aneurysm |
| Idiopathic hypocomplementemic tubulointerstitial nephritis with extensive tubulointerstitial deposits |

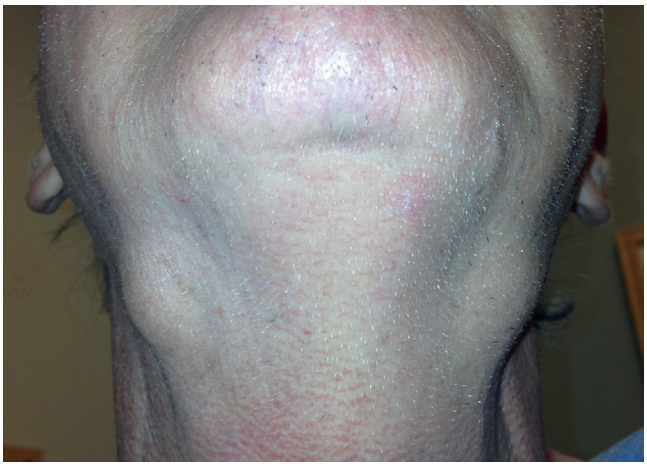

**Figure 121-1** Nontender enlargement of both submandibular glands in a patient with $IgG_4$-related sialadenitis of the submandibular gland. The patient had previously undergone a modified Whipple procedure (partial pancreatectomy) for what turned out to be type 1 ($IgG_4$-related) autoimmune pancreatitis.

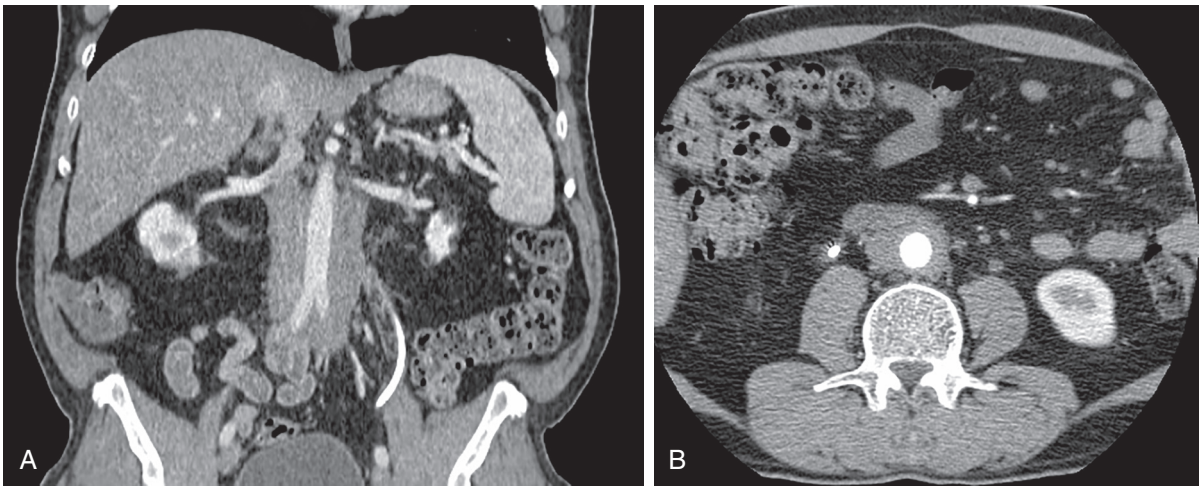

**Figure 121-2** Retroperitoneal fibrosis and periaortitis. **A,** Computed tomographic angiogram showing encasement of the infrarenal abdominal aorta by retroperitoneal fibrosis, extending inferiorly as far as the iliac arteries. **B,** This patient had also experienced right hydronephrosis caused by entrapment of the right ureter by the fibroinflammatory process. His right ureteral stent is visible on the left side of the figure.

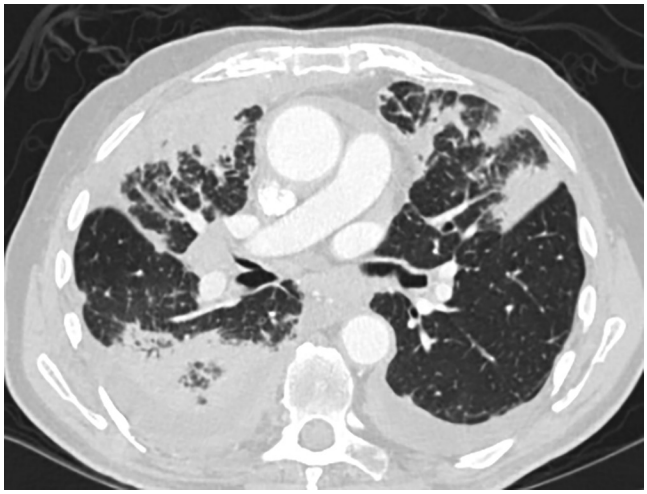

**Figure 121-3** $IgG_4$-related lung disease. Computed tomographic study of the lung showing thickening of the bronchial walls centrally, extensive pleural fibrosis anteriorly and posteriorly, and interstitial lung changes.

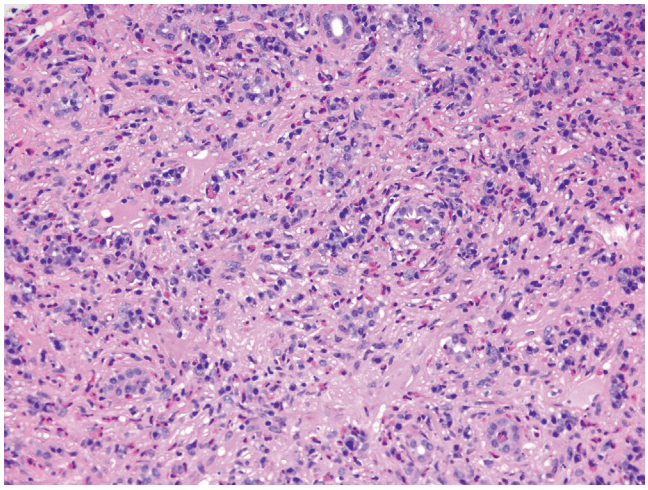

**Figure 121-4** $IgG_4$-related tubulointerstitial nephritis. A renal biopsy specimen demonstrates a decreased number of tubules in the renal interstitium, extensive lymphoplasmacytic infiltrate, numerous eosinophils, and storiform fibrosis throughout the tissue.

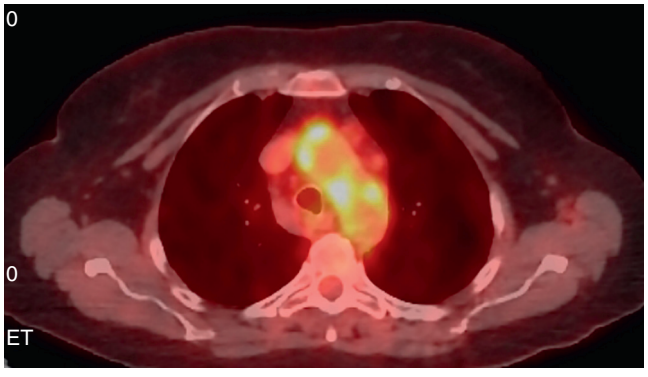

**Figure 121-5** A positron emission tomography study demonstrating increased 18F-fluorodeoxyglucose uptake in the aortic arch. The patient also had a subglottic mass and an inflammatory lesion encircling the left pulmonary artery. Results of the subglottic lesion biopsy are shown in Figure 121-9A and B.

complement pathway and participate in antibody-dependent cell-mediated cytotoxicity is attenuated substantially in comparison, for example, with the capabilities of $IgG_1$.[13]

Another unique feature of $IgG_4$ is its ability to form "half antibodies" through the process of Fab arm exchange. Fab arm exchanges result in the formation of IgG molecules with two different binding specificities.[13] Amino acid variation at the hinge region of $IgG_4$ permits the reduction of the disulfide bonds that join the two halves of an $IgG_4$ molecule. Recombination of the dissociated arms leads to the random formation of "asymmetric antibodies" composed of half-antibody fragments directed against different antigens.[12,13] The consequence is a reduced ability to cross-link antigens and form immune complexes.

In summary, the properties of the $IgG_4$ molecule appear to exert a suppressive effect on inflammation. Indeed, it has been demonstrated that the $IgG_4$ response develops after chronic antigen exposure as a part of a tolerogenic response.[12,13] Therefore, $IgG_4$ may play the role of a noninflammatory "antigen sink," the purpose of which is to "mop up" antigen through its monovalent binding in a process that tends to downregulate inflammation.[1]

## B Cell Lineage

Judging from the response of patients to rituximab, B cells and the cells of their lineage likely play an important role in $IgG_4$-RD.[14,15] The rapidity with which the serum $IgG_4$ concentration declines after B cell depletion suggests that the cells making most of the serum $IgG_4$ are short-lived plasmablasts and plasma cells. Plasmablasts are found in high concentrations in $IgG_4$-RD, regardless of the serum $IgG_4$ concentration.[9-11] Both total plasmablasts and $IgG_4^+$ plasmablasts appear to be good biomarkers for disease activity in $IgG_4$-RD, and their measurement is also useful in diagnosis. Flow cytometry gating for these cells is not widely available at this time, even though transcriptional profiling of whole blood has proved useful in other disorders. B cells and their lineage may play a variety of roles in $IgG_4$-RD, including the production of $IgG_4$ (although the centrality of $IgG_4$ to disease pathophysiology is debated). It is speculated that B cells and plasmablasts play important roles in antigen presentation to T cells.

## T Cells

More recent evidence suggests that T cells play a crucial and directory role in the pathogenesis of $IgG_4$-RD. $CD_4^+$ T cells are typically dispersed throughout localized $IgG_4$-RD lesions and are the most abundant cell found within affected tissues. The circulating plasmablasts in $IgG_4$-RD demonstrate intense somatic hypermutation, a hallmark of interaction with T cells within the germinal centers of lymph nodes.[16] Conflicting reports have implicated T helper (Th)1 cells and Th2 cells in the pathophysiology of $IgG_4$-RD.[17,18] Recent studies suggest that Th2 cells accumulate in the blood only in subjects with concomitant atopy.[19,20] The recent identification of a clonally expanded population of $CD4^+$ cytotoxic T lymphocytes in both the peripheral blood and fibrotic lesions of patients with $IgG_4$-RD suggests that these cells may be central to the disease.[16] These cytotoxic T cells make products such as granzyme B and perforin that

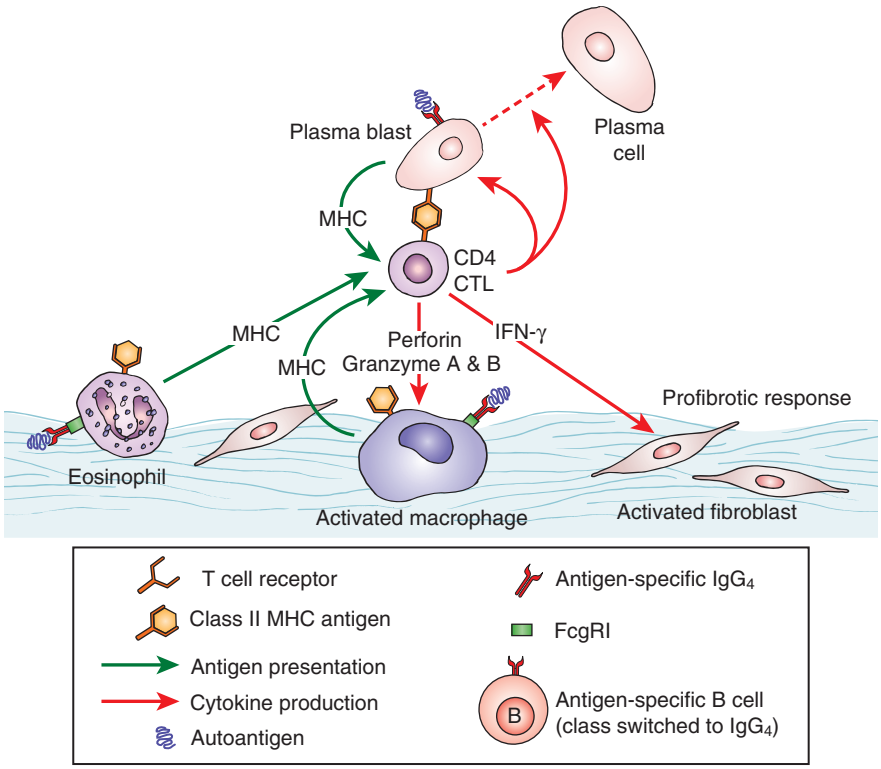

**Figure 121-6** Scheme of pathophysiology. CTL, Cytotoxic T lymphocyte; MHC, major histocompatibility complex.

are associated more commonly with $CD8^+$ T cells. Moreover, the interleukin (IL)-1 elaborated by these $CD4^+$ $SLAMF7^+$ cells may be an important mediator of the fibrosis.

It is attractive to consider that $CD4^+$ T cells orchestrating the disease are sustained by continuous antigen presentation by B cells. A T follicular helper cell response that is separate from the $CD4^+$ cytotoxic T lymphocytes is likely to be responsible for the development of germinal centers within lymph nodes (and involved organs). In theory, such T follicular helper cells could produce the cytokines (e.g., IL-4) that drive the $IgG_4$ class switch, culminating in the creation of $IgG_4$-secreting plasmablasts and long-lived plasma cells. The fact that B cell depletion does not lead to the complete normalization of serum $IgG_4$ concentrations implies the presence of long-lived plasma cells that continue to make this Ig.[14]

## Serum $IgG_4$ Concentrations

Serum $IgG_4$ measurements continue to play an important role in the diagnosis and management of $IgG_4$-RD, but $IgG_4$ levels must be considered from several angles.

### Dramatic $IgG_4$ Elevations in a Minority of Patients

A serum $IgG_4$ level is often the first diagnostic test ordered when $IgG_4$-RD is suspected. Large elevations of serum $IgG_4$ concentrations—for example, on the order of six to eight times the upper limit of normal for a given assay—strongly suggest the diagnosis. Patients with multiorgan disease can have dramatic elevations in serum $IgG_4$ concentrations, occasionally exceeding 4 mg/dL.[21] Patients with $IgG_4$-RD also often have elevations of other IgG subclasses (particularly $IgG_1$, $IgG_2$, and $IgG_3$), but the elevations of $IgG_4$ are usually disproportionate.[9]

### A Diagnostic Paradox

Despite the frequently striking serum $IgG_4$ concentrations observed in patients with this disease, an important paradox exists. Among patients with active disease whose cases are identified on the basis of histopathology rather than by elevations in serum $IgG_4$ concentrations, just over half of the patients have elevated serum $IgG_4$ concentrations before treatment.[9] In contrast, when cases were sought by querying a hospital laboratory database about the number of patients with abnormally high serum $IgG_4$ measurements, the sensitivity of an elevated serum $IgG_4$ concentration was 90%.[22] Two major points should be drawn from these studies. First, a large proportion of patients with biopsy-proven, clinically validated $IgG_4$-RD have normal serum $IgG_4$ concentrations, even before beginning treatment. Reliance upon serum $IgG_4$ concentration elevations for diagnosis, therefore, is certain to lead to a dangerous degree of underdiagnosis. Second, among patients with elevated serum $IgG_4$ levels, the range of values is extremely broad. The factors contributing to such variability in the $IgG_4$ response remain poorly defined.

### $IgG_4$ as a Biomarker of Disease Activity

Similar questions pertain to the ability of elevations in serum $IgG_4$ concentrations to predict disease flares. In a

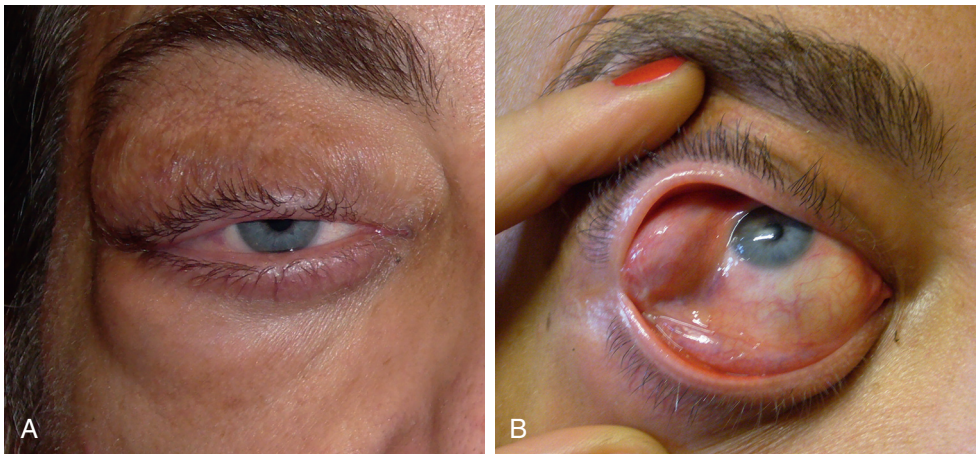

**Figure 121-7** Dacryoadenitis. **A,** Bulge of the superolateral portion of the right eye caused by lacrimal gland enlargement and enlargement of the extraocular muscles. **B,** The upper eyelid is everted, revealing the enlarged lacrimal gland.

large retrospective study of type 1 AIP from 17 centers in Japan,[23] serum $IgG_4$ levels declined in all patients after treatment with glucocorticoids but remained above the upper limit of normal in 63% of the patients despite good clinical responses. Thirty percent of the patients who relapsed had normal serum $IgG_4$ levels at the time of relapse. Thus serum $IgG_4$ concentrations should not be relied upon exclusively as an indicator of disease activity.

### Serum $IgG_4$ in Other Conditions

Mild $IgG_4$ elevations are common in a variety conditions that can mimic $IgG_4$-RD. Vasculitides such as granulomatosis with polyangiitis and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome), bronchiectasis, biliary diseases such as primary sclerosing cholangitis, pancreatic cancer, and numerous others can have confounding high serum $IgG_4$ concentrations, although they rarely if ever reach the highest values achieved by some patients with $IgG_4$-RD.[24] This phenomenon imposes additional limitations on the diagnostic interpretation of an elevated serum $IgG_4$ level.

In summary, substantial elevations in serum $IgG_4$ levels are useful in suggesting the diagnosis of $IgG_4$-RD but are not diagnostic in and of themselves. A large minority of patients with histopathologically confirmed disease—on the order of 40%—have normal serum $IgG_4$ concentrations. Finally, $IgG_4$ concentrations correlate only loosely with disease activity and are imperfect predictors of the need for additional treatment.

## CLINICAL MANIFESTATIONS

The presentation of $IgG_4$-RD is typically subacute. Symptoms and signs of organ dysfunction can be evident for months or even years before the diagnosis. Although weight losses of 10 to 30 lb can occur over months, fevers and hectic presentations are unusual. Fatigue commonly accompanies $IgG_4$-RD, particularly when the disease affects multiple organ systems. Many patients have arthralgias and other musculoskeletal symptoms, particularly enthesopathy, but frank arthritis is highly atypical and should signal other diagnoses.

### Orbits

Lacrimal gland enlargement (dacryoadenitis [Figure 121-7]) is the most common feature of ophthalmic disease in $IgG_4$-RD.[25] Proptosis can result from combinations of orbital lesions, such as pseudotumors that do not affect the lacrimal gland and inflammation and thickening of the extraocular muscles. Scleritis and nasolacrimal duct disease (obstruction) also can occur in $IgG_4$-RD, thereby mimicking granulomatosis with polyangiitis.

### Nervous System Disease

The brain parenchyma is seldom if ever involved, but $IgG_4$-RD is among the most common causes of "idiopathic" hypertrophic pachymeningitis. $IgG_4$-RD is also an established cause of hypophysitis.[26] $IgG_4$-related hypophysitis can lead to hormone deficiencies from both the anterior and posterior pituitary. MRI shows sellar enlargement and thickening of the pituitary stalk. MRI studies also often reveal perineural inflammation of peripheral nerves in the area of the orbit, particularly the trigeminal and infraorbital nerves.[27] Peripheral nerve lesions typically consist of perineural masses, often up to 3 cm in diameter. These masses are often observed on MRI in the absence of overt clinical manifestations but can lead to concern about the possibility of malignant growths.

### Salivary Glands

The triad of dacryoadenitis and enlargement of both the parotid and submandibular glands is a classic presentation of $IgG_4$-RD that for more than 100 years was known as Mikulicz's disease.[28-29] Isolated submandibular gland enlargement (see Figure 121-1) is also a common finding in people with $IgG_4$-RD, but parotid and sublingual gland disease can also be prominent. Xerostomia often accompanies $IgG_4$-RD, but this condition improves with immunosuppression (in contrast to Sjögren's syndrome). Biopsies of minor salivary glands can reveal $IgG_4$-RD, although the sensitivity of this procedure is lower than that of a major salivary gland biopsy (e.g., the submandibular gland). Fine-needle aspirates of major salivary glands are useful for excluding malignancy,

but excisional biopsies are usually required for diagnostic confirmation.

## Ear/Nose/Throat

Allergic rhinitis, nasal polyps, chronic sinusitis, nasal obstruction, and rhinorrhea are common in people with IgG4-RD. Mild to moderate peripheral eosinophilia and serum IgE concentration elevations that sometimes exceed ten times the upper limit of normal are common. The prevalence of atopy among patients with IgG4-RD is similar to that of the general population, but a subset of nonatopic patients has peripheral blood eosinophilia and elevated IgE levels,[19] which suggests that processes inherent to IgG4-RD itself rather than atopy per se contribute to the eosinophilia and IgE elevation. Circulating Th2 memory cells are found only in patients with IgG4-RD who have a pre-existing history of atopy.[20]

Mass lesions can occur in the sinuses, and destructive lesions in the middle ear and facial bones have been reported.[30,31] IgG4-RD can also lead to diffuse inflammation in the pharynx, hypopharynx, and Waldeyer's ring, frequently associated with mass lesions.[32] Tracheal inflammation and vocal cord involvement have also been described.

## Thyroid Gland

Riedel's thyroiditis has been linked convincingly to IgG4-RD.[33] Fibrosing Hashimoto's thyroiditis may also fall within the spectrum of IgG4-RD disease, but further study of this entity is required.[34] More controversial is the assertion that a substantial proportion of individuals with Hashimoto's thyroiditis also have an IgG4-related disorder. A form of thyroid disease referred to as "IgG4-related thyroiditis," distinct from Hashimoto's thyroiditis, is purported to exist,[35] but this assertion requires confirmation in other studies.

## Lymphadenopathy

The lymphadenopathy associated with IgG4-RD is typically either a generalized lymphadenopathy or localized disease adjacent to an affected organ.[36] The lymph nodes involved are generally 1 to 3 cm in diameter and nontender. Involvement of the cervical, supraclavicular, submandibular, axillary, hilar, mediastinal, para-aortic, retroperitoneal, and inguinal nodes is described. Establishing the diagnosis of IgG4-RD through lymph node biopsy is often difficult because it is unusual for lymph nodes to undergo the degree of fibrosis observed in other organs. At least five histopathologic variants of IgG4-related lymphadenopathy have been described.[37] One of these variants closely mimics Castleman's disease.

## Thoracic Aorta, Branches of the Aorta, and Coronary Lesions

IgG4-related aortitis, which often is suspected on the basis of an incidental radiologic finding, is also sometimes an unexpected finding at surgery. IgG4-related aortitis can lead to aneurysms or dissections in the thoracic aorta.[38-40] In contrast to giant cell and Takayasu's arteritis, which have a predilection for the primary aortic branches—particularly the subclavian arteries—IgG4-RD tends to spare these vessels, at least in terms of clinical manifestations. Small case series substantiate the concept that medium-sized blood vessels can also be affected by IgG4-RD. The relationship between the obliterative arteritis and obliterative phlebitis observed microscopically (see the Pathologic Features section) and larger vessel disease remains unclear. Definitive histopathologic investigations of primary aortic branch vessels have not been undertaken.[41] Coronary artery lesions in IgG4-RD, sometimes associated with aneurysm formation, are documented.[42]

## Chronic Periaortitis and Retroperitoneal Fibrosis

"Idiopathic" RPF is now considered to belong to a larger disease spectrum known as chronic periaortitis. The three major components of chronic periaortitis are IgG4-related RPF (see Figure 121-2), IgG4-related abdominal aortitis, and IgG4-related perianeurysmal fibrosis.[43] IgG4-RD is responsible for up to two-thirds of cases of "idiopathic" RPF.[43,44] Some cases of idiopathic RPF that do not appear to be part of the IgG4-RD spectrum can have similar presentations and can be distinguished from IgG4-RD through careful histopathologic and immunostaining studies.

Common presentations of IgG4-related RPF and chronic periaortitis are poorly localized pain in the back, flanks, lower abdomen, or thighs; lower extremity edema; and hydronephrosis from ureteral involvement. These presentations are generally subtle at first, subacute in onset, and nonspecific, leading to diagnostic delay. The disease targets three sites: (1) periaortic/arterial regions involving connective tissue around the abdominal aorta or its first branches; (2) periureteral areas, leading to ureteral obstruction and hydronephrosis; and (3) a plaque-like mass that broadly involves the retroperitoneum.

The classic lymphoplasmacytic infiltrate may no longer be evident in cases of longstanding duration, but both storiform fibrosis and obliterative phlebitis can often still be identified. The ratio of $IgG_4^+$ plasma cells to the total number of plasma cells in tissue may be more helpful diagnostically than the overall number of $IgG_4^+$ plasma cells per high-power field (hpf) in patients with advanced fibrotic disease.

## Lung

The greatest diversity of clinical and radiologic presentations occurs in the lung.[45] Thickening of the bronchovascular bundle, best appreciated on CT examination, underscores the tendency of IgG4-RD to track along bronchi and blood vessels, which course together.[46] Other radiologic features of IgG4-RD include pulmonary nodules, ground-glass opacities, pleural thickening, and interstitial lung disease. The interstitial lung disease mimics nonspecific interstitial pneumonitis and other forms of interstitial fibrosis (see Figure 121-3).

## Kidney

Tubulointerstitial nephritis (TIN) is the most characteristic form IgG4-related kidney disease (Figure 121-4). IgG4-

related TIN recapitulates the histopathology found in other organs.[47] $IgG_4$-related TIN is often distinguished from other organ manifestations of $IgG_4$-RD by profound hypocomplementemia. The basis of this hypocomplementemia remains poorly understood, but it appears unlikely to be explained by $IgG_4$ itself, because $IgG_4$ does not bind complement effectively. The hypocomplementemia could result from the formation of immune complexes that contain $IgG_1$ or $IgG_3$, subclasses that bind complement more effectively and are often elevated to a lesser degree.

CT scanning in $IgG_4$-related TIN can reveal substantial renal enlargement and hypodense lesions within the renal parenchyma. Advanced renal dysfunction and even end-stage renal disease can result. Proteinuria can develop, but the levels are usually subnephrotic. Kidneys affected by $IgG_4$-RD can undergo atrophy, even in the setting of good clinical responses to therapy.[48]

Membranous glomerulonephropathy also occurs in $IgG_4$-RD, but the pathophysiology of this entity appears to have a pathophysiology different from that of $IgG_4$-related TIN.[49] The anti-phospholipase A2 ($PLA_2$) receptor antibody now known to cause "idiopathic" membranous glomerulonephropathy is not associated with $IgG_4$-related membranous glomerulonephropathy.[50] It is interesting to note, however, that the anti-$PLA_2$ receptor antibody is primarily of the $IgG_4$ subclass.[51]

## Pancreas

The pancreas was the first organ recognized to have an association with elevated serum $IgG_4$ concentrations.[5,6,52] Two AIP subtypes exist, only one of which (type 1) is associated with $IgG_4$-RD. Type 1 AIP demonstrates the classic histopathologic findings of lymphoplasmacytic sclerosing pancreatitis. The histologic features of type 2 AIP, which is less common than type 1, include neutrophilic infiltration into the pancreatic duct epithelium.[53-55]

The most common clinical presentation of type 1 AIP is obstructive jaundice, induced by concomitant $IgG_4$-related sclerosing cholangitis. Secondary diabetes mellitus occurs in approximately half of all cases. The nearly diagnostic CT features of AIP include diffuse pancreatic enlargement with delayed enhancement and a capsule-like low-density rim (Figure 121-8).[55] Diffuse, irregular narrowing of the main pancreatic duct on endoscopic retrograde and magnetic resonance cholangiopancreatography is also highly specific for AIP. Endoscopic ultrasonography-guided fine-needle aspiration is a useful diagnostic approach to exclude pancreatic cancer and should be attempted before any empiric glucocorticoid trial is undertaken.[56] Pancreatic stones occur with increased frequency among patients with type 1 AIP.

## $IgG_4$-Related Sclerosing Cholangitis and Cholecystitis

$IgG_4$-related sclerosing cholangitis frequently occurs with type 1 AIP.[57] The histology of $IgG_4$-related sclerosing cholangitis includes obliterative phlebitis and transmural fibrosis with dense infiltration of $IgG_4^+$ plasma cells and T cells. $IgG_4$-related sclerosing cholangitis must be differentiated from both primary sclerosing cholangitis and hilar cholangiocarcinoma. Neither serum $IgG_4$ concentrations nor cholangiographic or cholangioscopic findings differentiate these diseases with clarity,[58-61] and thus an endoscopic transpapillary biopsy is usually required. Although cholangiocarcinoma can be excluded by endoscopic biopsy, the superficial nature of endoscopic biopsies limits their utility for diagnosing $IgG_4$-related sclerosing cholangitis.[61] $IgG_4$-related cholecystitis sometimes occurs with $IgG_4$-related sclerosing cholangitis. Thickening of the gallbladder wall is detected on imaging but is usually asymptomatic.

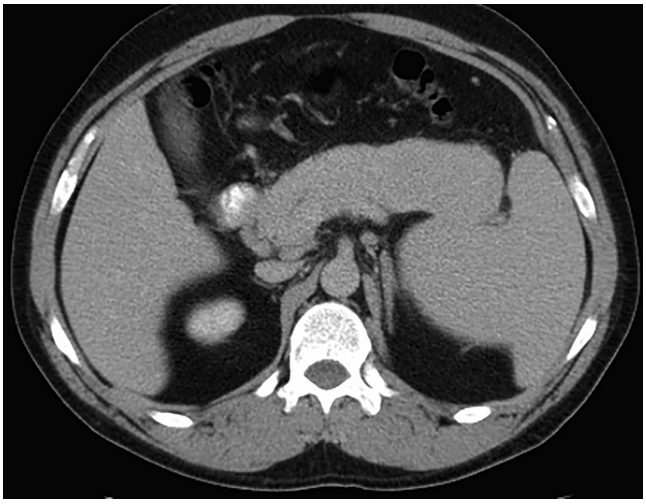

**Figure 121-8** Type 1 ($IgG_4$-related) autoimmune pancreatitis. Computed tomographic study showing an enlarged, sausage-shaped pancreas that has lost its normal markings.

## Other

Sclerosing lesions of both the mesentery and mediastinum are described.[62,63] Sclerosing mesenteritis often appears to originate at the mesenteric root. The ensuing process often merges imperceptibly with RPF and can evolve in a devastating manner, encasing vital organs and obviating any attempt at surgical resection. Fibrosing mediastinitis can lead to the compression of vital mediastinal structures from proliferation of invasive fibrous tissue. A review of 15 patients with fibrosing mediastinitis demonstrated that a substantial proportion of cases fall within the $IgG_4$-RD spectrum.[63] The relationship between these cases and antecedent histoplasmosis infections, if any, remains unclear.

Several clinical presentations of $IgG_4$-related skin disease have been reported. The most common cutaneous manifestation is the presence of erythematous papules. These lesions typically affect the region of the head and neck but have also been described on the trunk and extremities.[64] Among individuals with darkly pigmented skin, hyperpigmented lesions have been observed.

Biopsy-proven $IgG_4$-related prostatic disease leading to prostatic enlargement has been reported.[65] The diagnosis of $IgG_4$-related prostate disease is often made presumptively when the initiation of treatment for $IgG_4$-RD in other organs mediates abrupt symptomatic relief of "benign prostatic hypertrophy."

## PATHOLOGIC FEATURES

### Histologic Features

A defining feature of $IgG_4$-RD is the similarity of the histologic appearance regardless of the organ affected.[4] The hallmark morphologic findings include a dense lymphoplasmacytic infiltrate rich in $IgG_4^+$ plasma cells (Figure 121-9A and B). This lymphoplasmacytic infiltrate is enmeshed by an irregularly whorled fibrotic process that is termed "storiform" fibrosis (Figure 121-9C).[66,67] Obliterative phlebitis, resulting in destruction of the venous lumen, is another characteristic lesion observed in the majority of cases (Figure 121-10).[66] Obliterative arteritis is also observed in some organs, particularly the lung. Eosinophilic infiltration occurs in approximately 50% of cases, regardless of the organ involved.[66]

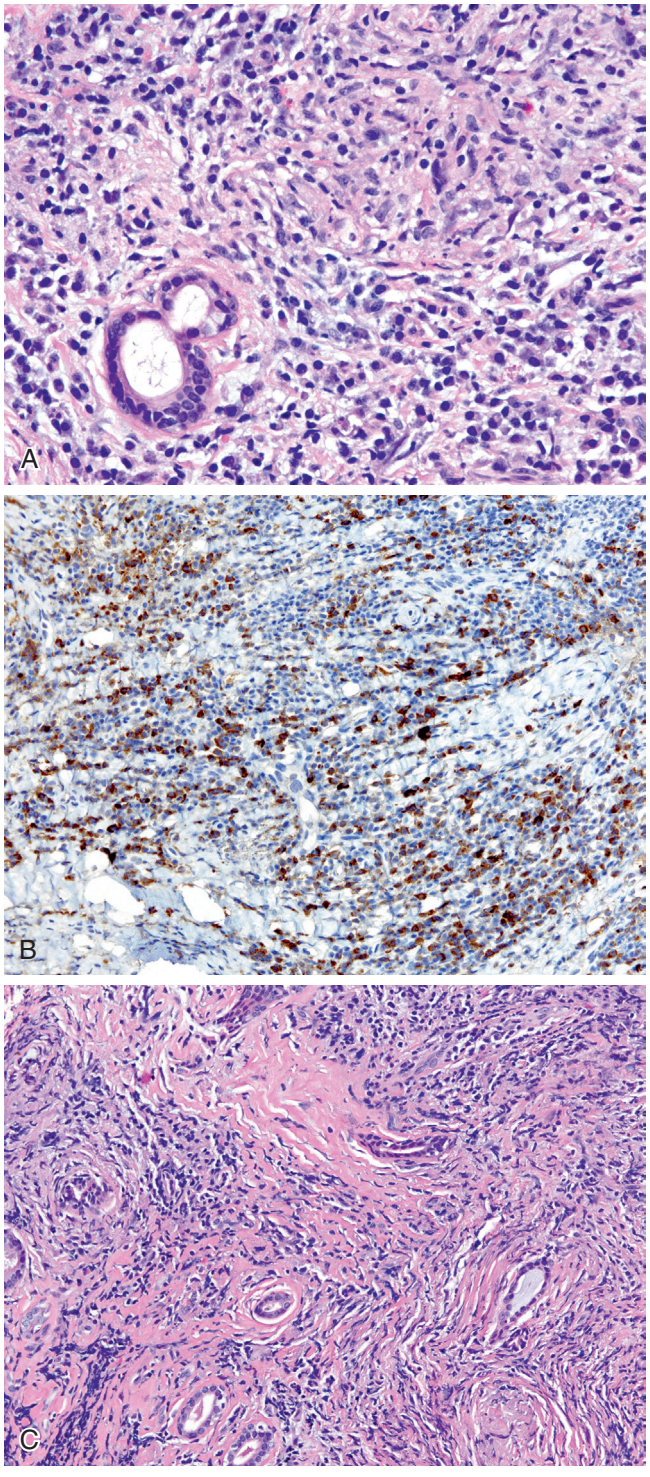

**Figure 121-9** A biopsy specimen of a subglottic lesion from the patient whose aortitis is shown in Figure 121-5 revealed a dense lymphoplasmacytic infiltrate (**A**), extensive infiltration by $IgG_4^+$ plasma cells (**B**), and storiform fibrosis (**C**). The tissue has a swirling pattern, characteristic of the type of fibrosis that is classic for $IgG_4$-RD.

### Immunostaining

The preponderance of plasma cells within tissue lesions stain for $IgG_4$. An increase in the number of $IgG_4^+$ plasma cells per hpf and an elevated $IgG_4^+/IgG^+$ plasma cell ratio can therefore support the diagnosis of $IgG_4$-RD, but careful clinicopathologic correlation and sound clinical judgment must be exercised in rendering the diagnosis of $IgG_4$-RD. An important issue pertains to the total number of $IgG_4^+$ plasma cells needed to regard a biopsy as being "diagnostic" of $IgG_4$-RD. In fact, no number of $IgG_4^+$ plasma cells within a biopsy is sufficient to support the diagnosis of $IgG_4$-RD on its own. Neither the number of $IgG_4^+$ plasma cells per hpf nor the $IgG_4^+/IgG^+$ plasma cell ratio is specific for the diagnosis of $IgG_4$-RD. Rather, the finding of the characteristic histopathology in the right clinical context allows the pathologist and clinician to reach the diagnosis in collaboration. "Positive" $IgG_4$ immunostaining lends additional support to the diagnosis of $IgG_4$-RD but is not diagnostic in and of itself.

One may expect fewer $IgG_4^+$ plasma cells in biopsy specimens from patients with fibrotic lesions such as RPF because of the overwhelmingly fibrotic nature of the disease at the time of biopsy in most patients. In such patients, as few as 10 $IgG_4^+$ plasma cells per hpf may be regarded as supportive of the diagnosis of $IgG_4$-RD, particularly if the remainder of the clinical and pathologic features are consistent with that diagnosis. In contrast, the number of $IgG_4^+$ plasma cells per hpf is generally much higher in biopsy specimens of the major salivary glands, lacrimal glands, pancreas, lungs, kidneys, and many other organs. Therefore, different criteria for appropriate cutoffs have been proposed.[66-68] A finding

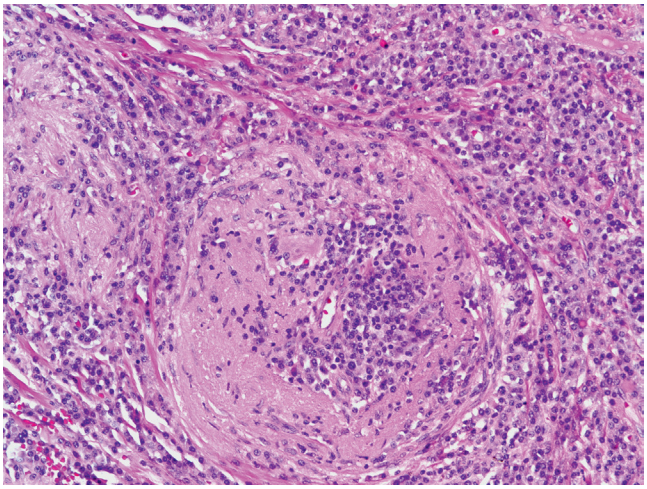

**Figure 121-10** Obliterative phlebitis. A vein observed within a lung biopsy specimen from a patient with $IgG_4$-RD. The lymphoplasmacytic infiltrate has completely obliterated the lumen of the lung.

of more than 30 $IgG_4^+$ plasma cells per hpf has good specificity for type 1 AIP, whereas more than 10 $IgG_4^+$ plasma cells per hpf has reasonable specificity for $IgG_4$-related TIN.[68,69]

The $IgG_4^+/IgG^+$ plasma cell ratio can also be a useful metric to aid in diagnosis. Most cases of documented $IgG_4$-RD have an $IgG_4^+/IgG^+$ plasma cell ratio greater than 40%. This value has been proposed as a criterion for diagnosis across all organs.[68] The $IgG_4^+/IgG^+$ plasma cell ratio can be particularly helpful in the setting of advanced fibrosis (e.g., in RPF), when the paucity of cells makes large concentrations of $IgG_4^+$ plasma cells unlikely.

### Morphologic Change of Affected Organs

Transformations in the gross pathology of affected organs occur. The pancreas and kidneys become diffusely enlarged. In contrast, ductal organs (e.g., the bile duct and bronchus) assume the appearance of a pipe stem, with diffuse wall thickening.[57]

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of $IgG_4$-RD varies according to the sites of organ involvement. Table 121-2 shows the broad differential diagnosis of this condition, by organ.

## TREATMENT

No randomized clinical trials have been performed to evaluate the comparative effectiveness of different treatment regimens, and the optimal treatment of $IgG_4$-RD is unknown. Current approaches to management are based on observational case series. The decision to treat is predicated upon patients' symptoms and the organ systems involved. Glucocorticoids are currently the first-line treatment for $IgG_4$-RD. Most data on the use of glucocorticoids are derived from the treatment of $IgG_4$-related pancreatitis (type 1 AIP) and have been extrapolated to the treatment of extrapancreatic $IgG_4$-RD. Treatment of $IgG_4$-related pancreatitis with glucocorticoids typically results in a symptomatic response within 2 weeks and remission at some point within 2 to 3 months in most cases.[21]

Many patients experience a relapse as glucocorticoids are tapered or discontinued, however, and the optimal approach to maintenance of remission remains unclear.[21] In a large cohort of patients with $IgG_4$-related pancreatitis, 34% of patients experienced a relapse after withdrawal of glucocorticoids. This figure probably underestimates the true number of relapses because patients often have recurrent manifestations of $IgG_4$-RD many years after the initial presentation.[70]

Because $IgG_4$-RD tends to involve a middle-aged to elderly patient population, extended treatment with glucocorticoids is particularly problematic because of heightened concerns for osteoporosis, diabetes, and infections. For this reason, there has been an interest in steroid-sparing agents, particularly in the subset of patients with refractory or recurrent disease. Few data suggest that conventional "steroid-sparing" agents such as azathioprine and mycophenolate mofetil are effective in the absence of concurrent glucocorticoids.[53]

**TABLE 121-2** Differential Diagnosis of $IgG_4$-Related Disease by Organ System

| Organ | Differential Diagnosis |
|---|---|
| Orbits and periorbital tissues | Lymphoma; Graves' disease; granulomatosis with polyangiitis; sarcoidosis |
| Ears, nose, and sinuses | Allergic disease; eosinophilic granulomatosis with polyangiitis (churg-strauss syndrome); granulomatosis with polyangiitis; sarcoma |
| Salivary glands | Lymphoma; Sjögren's syndrome; sarcoidosis; sialodocholithiasis |
| Meninges | Idiopathic hypertrophic pachymeningitis; inflammatory myofibroblastic tumor; granulomatosis with polyangiitis; giant cell arteritis; langerhans cell histiocytosis; sarcoidosis |
| Pituitary | Neoplasms; histiocytosis; hypophysitis: primary and secondary (sarcoidosis, ipilimumab-induced) |
| Lymph nodes | Castleman's disease; lymphoma |
| Thyroid gland | Thyroid lymphoma; differentiated thyroid carcinoma (mainly the papillary variant); other malignancy |
| Lungs | Malignancy (adeno- or bronchioloalveolar carcinoma); inflammatory myofibroblastic tumor; sarcoidosis; Castleman's disease; lymphomatoid granulomatosis; idiopathic interstitial pneumonia; Erdheim-Chester disease; inflammatory myofibroblastic tumor; granulomatosis with polyangiitis |
| Aorta | Primary large-vessel vasculitis (giant cell or Takayasu's arteritis); sarcoidosis; Erdheim-Chester disease; histiocytosis; lymphoma |
| Retroperitoneum | Lymphoma; sarcoma; Erdheim-Chester disease |
| Kidney | Lymphoma; renal cell carcinoma; drug-induced tubulointerstitial nephritis; pauci-immune necrotizing and crescentic glomerulonephritis; sarcoidosis; Sjögren's syndrome; systemic lupus erythematosus; mixed cryoglobulinemia |
| Pancreas | Pancreatic cancer; type 2 autoimmune pancreatitis |
| Biliary tree | Pancreatic cancer; cholangiocarcinoma; primary sclerosing cholangitis |
| Liver | Cholangiocarcinoma; hepatocellular carcinoma; primary sclerosing cholangitis |

Treatment with rituximab to induce B cell depletion has yielded promising results.[14,71] A recent prospective trial of rituximab appears to validate smaller case series indicating that B cell depletion is an effective approach to the treatment of IgG4-RD.[15] Further investigation is needed to establish the optimal use of rituximab in IgG4-RD and to test methods of monitoring the clinical response.

CHAPTER 122

# Arthritis Accompanying Endocrine and Metabolic Disorders

Soumya D. Chakravarty • Joseph A. Markenson

**KEY POINTS**

- **Endocrine disorders can initially present or manifest with a multitude of musculoskeletal signs and symptoms. Additionally, endocrine manifestations of underlying autoimmune disorders are common and need to be recognized promptly.**
- **Whereas Cushing's disease arises from excessive secretion of adrenocorticotropic hormone as a result of a pituitary adenoma, exogenous Cushing's syndrome can result from chronic corticosteroid therapy and should be vigorously sought and promptly treated.**
- **Many musculoskeletal complications observed in people with diabetes mellitus can be attributed to modifications in connective tissue, leading to fibrosis and tendinopathies. Underlying diabetic neuropathy can result in a debilitating and irreversible osteoarthropathy.**
- **Prompt and thorough evaluation for underlying thyroid disease in patients presenting with musculoskeletal symptoms is critical because in most instances appropriate therapy can alleviate such manifestations.**
- **Primary hyperparathyroidism often causes a crystal-induced arthropathy consistent with calcium pyrophosphate dihydrate deposition.**

Rheumatic manifestations are often the initial presentation of systemic illnesses. Each endocrine disorder has its own set of arthritic symptoms that can mimic or present as definitive rheumatic diatheses, requiring a high degree of vigilance and a thorough assessment of patients presenting with such varied symptoms. Both rheumatologists and general internists should be well versed in identifying the manner in which components of the musculoskeletal system are affected by diseases of the endocrine system. Additionally, recognition that endocrinopathies can arise in the course of treating rheumatic illnesses, such as with the use of corticosteroids, is critical in minimizing or reversing any potential adverse sequelae in these patients. This chapter will describe the common musculoskeletal manifestations of endocrine disease encountered in the clinical setting.

## ADRENAL GLAND DISORDERS

In 1932, Harvey Cushing described several rheumatic conditions, including osteoporosis, avascular necrosis, myopathy, and synovitis, later to be termed collectively as part of Cushing's syndrome. Since then, our understanding of the syndrome has evolved, with identification of two major categories. The first category, termed *primary Cushing's disease*, is caused by a pituitary adenoma, a benign malignancy that results in oversecretion of adrenocorticotropic hormone (ACTH).[1,2] The second and more common manifestation, exogenous Cushing's syndrome (also termed *hypercortisolism* or *hyperadrenalism*), occurs as a result of the use of chronic corticosteroid therapy and can have a variety of adverse effects on the musculoskeletal system.[3] Avascular necrosis generally occurs after prolonged use of high-dose corticosteroids but can be observed months or even years after the discontinuation of steroids.[4,5] Less commonly, it can be associated with short courses of therapy or intermittent high-dose intravenous therapy; consequently, the risk for avascular necrosis should always be considered during one's assessment.[5-7]

Steroid myopathy can occur in patients treated with corticosteroids and presents as extreme muscle weakness and pain that is most often pronounced around the pelvic girdle. This muscle weakness and pain may either occur suddenly or be insidious in onset.[8-10] Usually a muscle biopsy demonstrates type 2 fiber atrophy, whereas electromyography shows a myopathic picture. Muscle enzymes are usually not elevated, and the condition gradually improves as corticosteroids are tapered or discontinued completely.[11] A similar picture has been reported in Cushing's disease.[12] As part of this clinical presentation, osteopenia, as well as progression to osteoporosis, can be related to the corticosteroid dose and duration of disease, more frequently occurring at dosages greater than 7.5 mg/day of prednisone or its equivalent[13-15]; several treatment regimens reported including the use of calcium, vitamin D ($D_3$), bisphosphonates, and teriparatide (recombinant parathyroid hormone [PTH]).[16,17] Interestingly, recent work performed to elucidate whether allelic variants in the vitamin D receptor (VDR), which has been associated with osteopenia, may have an effect on bone mineral density (BMD) in people with Cushing's disease was unable to demonstrate an association between BMD and common VDR polymorphisms.[18] Finally, the myopathy associated with Cushing's disease can mimic other primary musculoskeletal disorders, such as statin-induced myopathy, polymyalgia rheumatica, or polymyositis, and thus should also be included in the differential diagnosis.[19]

Adrenal insufficiency can be categorized into three subgroups depending on the level at which the hypothalamic-pituitary-adrenal (HPA) axis is involved.[19] Primary adrenal insufficiency, or Addison's disease, is caused by damage to

the adrenal gland. The secondary form results from insufficient ACTH production by the anterior pituitary gland, whereas the tertiary form is a consequence of inadequate corticotropin-releasing hormone (CRH) secretion by the hypothalamus. Acute adrenal insufficiency, also known as adrenal crisis, can be a life-threatening condition and is characterized by shock. The cause of primary adrenal insufficiency is believed to be primarily autoimmune in nature and is associated with hypotension, nausea, abdominal pain, weight loss, generalized weakness, and hyperpigmentation.[20] Secondary adrenal insufficiency usually results from destruction of the anterior pituitary gland or ACTH deficiency, with precipitating events such as hemorrhage, thrombosis, or granulomatous diseases like sarcoidosis. The chronic use of corticosteroids and their subsequent cessation can trigger secondary or tertiary adrenal insufficiency.[21] The mechanisms underlying corticosteroid-induced adrenal insufficiency are varied and include decreased production of CRH and adrenal atrophy, particularly after chronic ACTH deficiency. Addisonian crisis, which can be a life-threatening event, has been observed in patients receiving even physiologic doses of corticosteroids. Because the likelihood of HPA axis suppression and the inability to respond to medical and surgical stressors is very high in individuals treated with more than 5 mg/day of prednisone or its equivalent, transiently increasing steroid dosing in the acute setting is advisable.[22-24]

## ACROMEGALY

Acromegaly is caused by hypersecretion of growth hormone (GH) and subsequently of insulin-like growth factor (IGF)-I as a result of a GH-secreting pituitary tumor. Other causes, such as increased GH-releasing hormone (GHRH) production from hypothalamic tumors, ectopic GHRH production, and ectopic GH secretion from nonendocrine tumors, are rare. Acromegaly occurs most commonly in middle-aged men and women. Its prevalence is 4.6 cases per million population, and the incidence is 116.9 new cases per million per year.[25] Hypersecretion of GH affects all organs, causing disturbances in structure, endocrine function, and metabolism. GH released into circulation stimulates production of IGF-I, which is the primary mediator of GH and stimulates growth of soft tissue and fibroblast proliferation, causing an increased thickening of connective tissue. Local manifestations also occur with growth of a pituitary adenoma as it compresses local structures and causes neurologic symptoms.[26,27]

Musculoskeletal manifestations of acromegaly present as arthralgias of the large joints (i.e., knees, hips, and shoulders). Patients may experience proximal muscle weakness, although muscle enzymes are generally normal and biopsy specimens may demonstrate variation in fiber size without inflammation. Fibrous synovial thickening and/or bony overgrowth in the proximal interphalangeal (PIP) and distal interphalangeal joints is reported in 50% of patients.[28] Radiographic changes include an enlarged sella turcica, increased thickness and enlargement of the frontal sinuses, elongation of the mandible, soft tissue thickening, broad metacarpals and phalanges, prominent distal tufts, widened joint spaces (due to cartilage hypertrophy), increased thickness of the heel pad, broadening of the sternal ends of the ribs, kyphosis, and enlargement of the vertebral bodies.

Morning stiffness and joint swelling are rare, and the severity of musculoskeletal complaints seems to correlate with the severity of disease. Carpal tunnel syndrome (CTS) occurs in approximately 60% of patients with acromegaly and is frequently bilateral.[29,30] GH secreted by the anterior pituitary acts on hepatocytes to secrete somatomedins, which have stimulatory effects on bone and cartilage, including chondrocyte replication, synthesis of proteoglycans, collagen, osteoblastic proliferation, and increased bone collagen (resulting in increased bone mass).[31] Somatomedins also have insulin-like activity on muscle and fat. Treatment is aimed at decreasing the size of the adenoma (surgically, using ultrasound or laser), and success may not result in changes in the musculoskeletal findings or symptoms.

Arthralgia, as originally described by Pierre Marie in 1886, is one of the most commonly reported symptoms of people with acromegaly, affecting up to 75% of patients. Involvement of large peripheral joints (i.e., the shoulder, knee, and hip) is experienced by 60% to 70% of patients. Back pain may be a particularly troubling feature of acromegaly. Approximately 50% of patients have axial arthropathy, mainly affecting the lumbar area. Patients report a dull, diffuse pain in the lumbar region.[32] Other reported symptoms relate to limited range of movement, joint instability, and joint deformation. Ossification of the anterior surface of vertebral bodies is common and in more severe cases can bridge the disk space, resembling the diffuse idiopathic skeletal hyperostosis syndrome. Biermasz and colleagues[33] reported that a high prevalence of self-reported joint symptoms persisted despite successful long-term treatment of acromegaly. These joint problems were an important indicator of impaired quality of life.[33]

### Bone Mass and Quality in Acromegaly

Although acromegaly is often included in lists of endocrinopathies associated with osteoporosis because of increased bone turnover, some investigators have reported normal or increased bone mass in individuals with this disorder.[34] During childhood, GH secretion stimulates linear bone growth via its effect on IGF-I. The effects of GH secretion due to acromegaly on skeletal mass and bone metabolism in adults have been somewhat conflicting. GH and IGF-I have a stimulatory effect on osteoblast function, and several studies indicate a potential anabolic effect of GH, at least on the cortical bone. People with acromegaly had significantly higher levels of osteocalcin than did control subjects. Osteoporosis occurs rarely in individuals with acromegaly, and if present, it may be a result of hypogonadism. Acromegaly causes an increase both in bone apposition and resorption, and as a result, data on bone mass are controversial, generally because different skeletal sites are reported, different equipment is used for measurement, and data for groups have been reported without regard to comparison of sex and gonad status. Data on cortical bone generally show a normal or even increased BMD (regardless of the gonadal status), whereas discrepant data are seen with measurement of trabecular bone. However, acromegaly does confer an increased risk of morphometric vertebral fractures, which seems to correlate with acromegaly activity and its duration

but can persist after biochemical control is achieved.[35] Unfortunately, especially in post-menopausal women, these osteoporotic vertebral fractures often can be asymptomatic and thus are underdiagnosed.[35,36]

## HYPOTHALAMIC-GONADAL AXIS

Female-to-male ratios differ among connective tissues diseases. The ratio for rheumatoid arthritis (RA) is 3:1, with the exception of juveniles and older adults. Systemic lupus erythematosus (SLE) has a female-to-male ratio of 9:1, and in RA, the incidence is higher in post-menopausal as opposed to pre-menopausal women.[37] Adult men have a significant delayed onset of disease. Masi and Kaslow[38] and Petri[39] have suggested that these findings may be due to gonadal hormones with protection against RA in younger men (as a result of testosterone) and a predisposition to SLE in women (as a result of estrogens). In a longitudinal study of the levels of total testosterone, sex hormone–binding globulin, and luteinizing hormone (LH) in 41 males with early RA (naïve to disease-modifying anti-rheumatic agents [DMARDs] at study entry) over 2 years,[40] it was only in male patients younger than 50 years that lower baseline levels of testosterone were found compared with control subjects. When treated with DMARDs, the males who responded with decreased disease activity (as measured by Disease Activity Score–28 and the Health Assessment Questionnaire) also demonstrated significantly increased levels of testosterone. Changes in testosterone levels in patients older than 50 years were marginally better after DMARD treatment, and LH levels in both groups were unchanged (although lower in men older than 50 years). The consequence was improvement of the hypothalamic–pituitary–gonadal (HPG) axis at the gonadal level but not at the HPA level. In patients with RA, both the HPG and HPA axes have been reported to respond abnormally to inflammation and stress. The important question of whether inflammation decreased the HPA axis (increasing the risk for RA) and whether treatment reversed this risk was not answered. As pointed out by Masi et al.,[40] addressing this question would have required calculating baseline levels for these hormones prior to the onset of disease.

Adrenal glucocorticoids, secreted in response to ACTH stimulation, are considered to be among the key factors involved in the regulation of immune responses. It follows that dysfunction of the HPA axis caused by its inherited or acquired downregulation could create a predisposing environment for autoimmunity development.[41] Specific gene variants have been associated with several changes in HPA axis reactivity, resulting in suboptimal cortisol levels during challenges.[42] In addition to genetic predisposition, some early life events appear to program HPA function in adulthood. Hence this process could contribute to the development of various diseases, including RA, as seen in animal models of arthritis.[43,44]

### Adrenal Androgens in Rheumatoid Arthritis

Glucocorticoids play a role in regulating the expression of peptide genes in corticotropin-releasing hormone neurons that encode ACTH, thereby functioning as negative feedback to the HPA axis.[45] However, considerations of trophic (cell mass/competence) influences on the amount of hormones may occur at the adrenal gland level.[46] Adrenal glands of patients with pre-menopausal onset RA may have relatively deficient mass capacity of their endocrine function, particularly in the zona reticularis production of adrenal androgens, resulting in dissociation of glucocorticoids and adrenal androgens.[47] This phenomenon could result in functional and anatomic changes in the zona reticularis of the adrenals. Evaluation of androgen concentrations in patients with RA showed decreased dehydroepiandrosterone sulfate (DHEAS) in pre-menopausal women and decreased testosterone levels in men.[48] In a study of 50 human leukocyte antigen RA identical post-menopausal discordant sibling pairs, significantly lower levels of DHEAS correlated with disease severity and duration.[49] A prospective study showed decreased DHEAS levels in 35 women before disease development.[48] Another study reported no significant differences between 116 patients and 329 control subjects.[50] In addition, patients not treated with glucocorticoids have altered steroidogenesis of DHEA and DHEAS. Combined lower DHEAS and lower baseline cortisol levels could indicate adrenocortical hypocompetence. In a previous study, 40% of pre-menopausal women with RA were identified with combined relatively lower basal cortisol and lower DHEAS levels.[51] This finding might suggest decreased basal adrenal function and a consequent impact on immune function.

## DIABETES MELLITUS

Among individuals with diabetes mellitus (DM), an increased frequency in rheumatologic disorders has been observed compared with healthy control subjects.[52,53] In people with long-standing diabetes, connective tissue is subjected to various modifications, ranging from glycosylation of proteins to microvascular damage to blood vessels and nerves and deposition of extra-cellular matrix proteins in skin and periarticular areas. Cumulatively, this modification can result in a wide spectrum of musculoskeletal disorders and complications.[52,53]

### Shoulder

Adhesive capsulitis, or frozen shoulder, represents the most common form of shoulder involvement in diabetes, reportedly occurring in approximately 20% of diabetic patients.[54] A recent longitudinal study demonstrated that the hazard ratio of developing adhesive capsulitis for the diabetes group compared with the nondiabetes group was 1.333 (95% confidence interval [CI], 1.24 to 1.44, $P$ <0.0001).[55] Patients generally report shoulder stiffness and impaired external and internal range of motion. Another manifestation to consider with diabetics includes calcific shoulder tendonitis, which occurs three times more often in these patients compared with individuals without diabetes and involves periarticular calcium hydroxyapatite deposition, predominantly in the area of the rotator cuff tendons.[56]

### Hands

Involvement of the hands in diabetic patients is observed in more than 30% of patients and can present in a myriad

of forms, including trigger finger, flexor tenosynovitis, Dupuytren's contracture, and/or "stiff hand" syndrome.[57-60] Incidentally, the onset of these manifestations often predicts increased renal, ophthalmologic, and other complications of DM. Trigger finger results from the occurrence of stenosing flexor tenosynovitis, which drives proliferation of fibrous tissue in the tendon, particularly when the tendon passes through the fibrous ring or pulley. De Quervain's tenosynovitis entails the same mechanism at the radial styloid with thickening of the extensor pollicis brevis or the adductor pollicis longus tendon and occurs in 17% to 23% of patients with DM.[61] Dupuytren's contracture (palmer thickening of the flexor tendons) initially was reported in 15% to 21% of diabetic patients.[62] Flexion contractures of the fingers can occur, usually involving the fourth digit, but the second through fifth digits also can be involved. Interestingly, a study demonstrated a positive result with injections of collagenase clostridium histolytic for the treatment of Dupuytren's contracture.[63] Finally, diabetic "stiff hand" syndrome (or diabetic cheiroarthropathy)—a fibrosing syndrome often resembling scleroderma with features of thick, tight, and waxy skin—results in contractures at the metacarpophalangeal (MCP) and PIP joints.[57,64] This symptom is classically manifested in the advanced stages of the process by the patient's inability to press his or her palms together completely without a gap remaining between opposed palms and fingers and is known as the "prayer sign."

CTS can be a frequent complication of diabetes, occurring in up to 20% of diabetic patients. The mechanisms underlying median nerve entrapment involve the same aspects of connective tissue modulation in diabetes as previously mentioned.[65] Associated motor weakness also may occur as a consequence of median nerve compression and should be assessed. Testing in the form of an electromyographic (EMG)/nerve conduction velocity study can confirm the diagnosis of CTS.[66] More recently, ultrasonography has also become a valuable tool for confirming the diagnosis of CTS.[67,68] Ultrasonography permits detection of changes in the shape of the median nerve, can assist in ruling out anatomic variants, and can determine whether any space-occupying lesions such as ganglion cysts or tenosynovitis are also present.[67,68]

### Feet

Patients with DM often present with a diabetic neuropathy and its associated arthropathy, known as diabetic osteoarthropathy or Charcot's arthropathy.[69,70] Diabetic osteoarthropathy is rare; it is seen in people with long-standing disease and in both type 1 and type 2 diabetes.[69,70] The pathogenesis is believed to be neurovascular rather than neurotraumatic (resulting from decreased sensitivity of nerve endings) or caused by reduced flow as a result of arterial sclerosis of small vessels.[71] Because of neuropathy involving the sympathetic nervous system, patients with diabetes have increased blood flow to subchondral bone, resulting in increased osteoclastic activity and bone resorption. This phenomenon occurs even in the absence of peripheral vascular disease, resulting in bone fatigue and disorganization. It appears radiographically as progression from localized osteopenia to osteolysis of subchondral bone, fragmentation of bone and cartilage (part of which may be come embedded in synovial tissue), and sclerosis.[72] In addition to plain radiography, MRI and bone scintigraphy can be useful studies in evaluating the extent of disease. Joints involved in order of frequency include the ankle, metatarsophalangeal, and tarsometatarsal. This distribution differentiates diabetic arthropathy from tabes dorsalis in which the knee is more commonly involved. The pathogenic mechanism active in DM that can cause tissue damage is multifactorial. One possibility with regard to chondrocytes includes the role of receptors for advanced glycation end products (which are increased in individuals with diabetes and are mediators of inflammation and increased atherosclerosis), thereby upregulating matrix metalloproteinases that are involved in inflammation.[73-75]

### Muscles

Diabetic muscle infarction, a rare condition marked by spontaneous infarction of muscle tissue with no preceding injury, occurs largely in patients who are considered "brittle diabetics."[76] Characteristically, these patients will have accumulated numerous microvascular sequelae from their uncontrolled disease. Clinically, patients will present with abrupt onset of pain and swelling, usually involving the thigh or calf muscles, and creatine phosphokinase (CPK) levels may be normal or elevated.[76] MRI using T2-weighted imaging may be useful in arriving at the diagnosis, with confirmatory testing involving an incisional muscle biopsy and demonstration of muscle edema and necrosis.

### Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by ossification of the anterior longitudinal ligament of the spine, can involve various other extraspinal ligaments, and is generally accompanied by osteophyte formation (Figure 122-1). However, intervertebral disk spaces and sacroiliac joints are commonly spared. A high incidence of DISH has been demonstrated in a cohort of patients affected by both clinically active and subclinical DM (both type 1 and type 2), as well as in obese patients.[77] A more recent study found that individuals in their fifth decade of life are more likely to be affected by DISH if they were obese, had a first-degree relative with either DM or hypertension, had lumbar or thoracic spinal pain, and were affected by enthesopathies or tendonitis.[78] The likelihood of relatively young patients with three or more of these clinical parameters being affected by DISH was six times higher compared with age- and sex-matched control subjects ($P = 0.004$).[78]

## HYPOTHYROIDISM

The most common cause of primary hypothyroidism in the United States is autoimmune (Hashimoto's thyroiditis [HT]; also known as chronic autoimmune thyroiditis), with an occurrence of 3.6/100 person-years in females and 0.8/1000 person-years in men.[79-81] Other causes include pituitary adenoma or Sheehan's syndrome, surgical resection, iodine deficiency, deficiency in the iodothyronine synthetase pathway, or use of certain drugs (lithium or

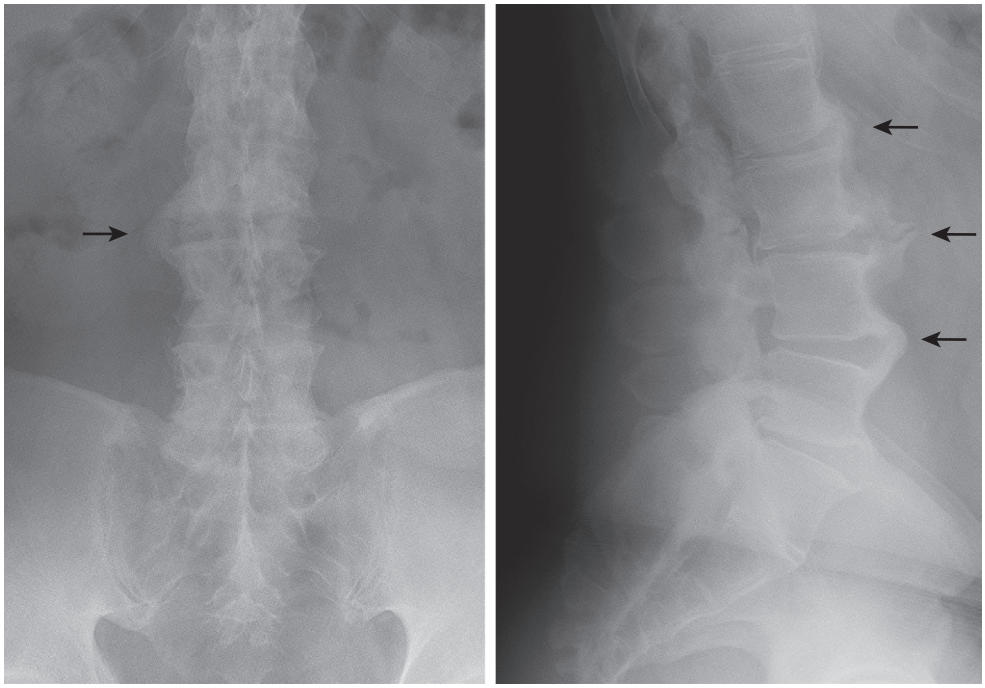

**Figure 122-1** A patient with diffuse idiopathic skeletal hyperostosis, as seen on anterior-posterior *(left)* and lateral *(right)* views. Calcifications of the anterior longitudinal spinal ligament are observed *(arrows)*. With advanced disease, these calcifications will typically progress into osteophytes that can extend across multiple vertebrae.

amiodarone). Hypothyroidism often presents with a characteristic symmetrical arthropathy involving stiffness of the joints of the hands and knees. Upon palpation, the joints feel "gelatinous," and aspiration of fluid is usually non-inflammatory and viscous, with high levels of hyaluronic acid. Calcium pyrophosphate dehydrate (CPPD) crystals are often found, and hypothyroidism should be included in the differential diagnosis of joints that demonstrate CPPD crystals upon aspiration.[82] The conditions associated with CPPD crystal deposition include:

- Hyperparathyroidism
- Familial hypocalciuric hyperkalemia
- Hemochromatosis
- Hemosiderosis
- Hypophosphatasia
- Hypomagnesemia
- Hypothyroidism
- Gout
- Neuropathic joints
- Aging
- Amyloidosis
- Trauma, including surgery

In patients with hypothyroidism, a myopathy has been reported that presents with pain, cramps, stiffness, proximal weakness, fatigue, elevated CPK levels, abnormal muscle disease on biopsy (atrophy of type II fibers and an increase in type I fibers), and hypercholesterolemia.[83,84] Hoffman's syndrome is a rare disorder of hypothyroidism manifesting with increased muscle mass (pseudohypertrophy in addition to the other aforementioned manifestations). Kocher-Debré-Semelaigne syndrome is a disorder of infancy (cretinism) presenting with similar pseudohypertrophy in mothers who have deficient levels of iodine.[85] Most symptoms of myopathy resolve upon treatment with thyroid hormone. Explanations for the effect of thyroid hormone on muscle include delayed contraction and relaxation (related to a change from fast to slow muscle fibers), alteration in myosin heavy chain gene forms, and impaired glycogenosis.[86] A neuropathy such as CTS can also be the initial manifestation of hypothyroidism. The mechanism for compression is thought to be a result of the accumulation of glycosaminoglycans within the surrounding tissues. One systematic review of 4908 patients with CTS found a pooled odds ratio of 1.4 (95% CI, 1.0 to 2.0) for the prevalence of concomitant hypothyroidism compared with healthy control subjects.[87]

## THYROID DISEASE

Patients with hyperthyroidism because of Graves' disease may present with pretibial myxedema and ophthalmopathy. The myxedema appears as nodules (usually 1 cm or larger) over the pretibial surface. They are composed of hyaluronic acid, are pink to purple in color, and are painless.[88,89] Patients with Graves' disease can also have proximal muscle weakness, associated shoulder adhesive capsulitis, loss of muscle mass, and weight loss. Most of these manifestations will correct with treatment.[90] Nail changes, onycholysis, and clubbing (thyroid acropachy) may be associated with periostitis around the metacarpal joints, as well as soft tissue swelling of the digits. Unfortunately, this condition may not return to normal when the patient is treated.[91,92]

A common and serious manifestation of hyperthyroidism is osteopenia and osteoporosis. Treatment with thyroid

hormone to achieve a normal level of thyroid-stimulating hormone (TSH), as well as adjusting the dose of thyroid replacement in hypothyroid patients, is essential. Achieving improvement in BMD (as measured by bone densitometry) in patients with thyroid disease is important.[93,94]

## Thyroid Disorders in Patients with Rheumatic Disease

In a recent prospective trial of 201 patients with rheumatic disease and 122 age matched healthy control subjects, mean TSH values of the patients with rheumatic disease and the control subjects were 3.1 ± 2.7 mIU/L and 1.9 ± 0.8 mIU/L, respectively ($P$ = 0.004).[95] The mean fT4 value of the patients with rheumatic disease was 1.43 ± 0.67 ng/dL, whereas that of the control subjects was 1.58 ± 0.68 ng/dL ($P$ <0.001), and thyroid autoantibodies were significantly higher in patients with rheumatic disease versus control subjects ($P$ <0.001).[95] A cohort of patients with and without RA from the Mayo Clinic was studied. No difference was found in the incidence of hypothyroid disease between patients with RA and non-RA control subjects. However, the presence of hypothyroidism in patients with RA was positively correlated with increased cardiovascular disease in the RA population even after adjustment for other traditional risk factors.[96] In a group of euthyroid patients with HT and no well-defined connective tissue disease, 98% presented with arthralgia and 59% with fibromyalgia, 28% had Raynaud's disease, and 26% had sicca symptoms.[97] Arthritis was radiographically present in 88% of these patients (arthritis of the spine accounted for 45%). TSH levels correlated with anti-thyroid peroxidase (anti-TPO) antibodies, but not erythrocyte sedimentation rate nor anti-thyroglobulin (anti-TG) antibody levels. The authors concluded that rheumatic manifestations frequently occur in patients with CTL in the absence of overt thyroid dysfunction.[97]

The occurrence of chronic HT, as well as hypothyroidism, is common in the general population, making it difficult to ascertain whether the incidence of either is increased in patients with connective tissue disease.[81] Two exceptions may be scleroderma in which fibrosis is the cause of hypothyroidism and congenital heart block in children of hypothyroid anti-Ro/SS-A mothers. Medications used to treat various connective diseases, as well as the disease itself, can affect thyroid function. For example, glucocorticoids inhibit TSH secretion, thereby slightly lowering serum thyroid hormone concentrations. Aspirin and NSAIDs may lower serum thyroid hormone by interfering with the binding to their carrier proteins.

## Systemic Lupus Erythematosus

Anti-thyroid antibodies are present in 15% to 20% of patients with SLE.[98] Concomitant hypothyroidism is estimated at 5.7% (five times greater than expected), as opposed to hyperthyroidism, occurring at 1.7% (similar to the normal population). This association may be genetic, as noted in a study of multiplex SLE families in which 35 of them who also had autoimmune thyroid disease demonstrated a linkage with 5q14.3-15 (the major susceptibility locus for SLE also found in autoimmune thyroid disease). This finding suggests that 5q14.3-15 harbors a susceptibility gene shared by patients with SLE and autoimmune thyroid disease.[99]

A common reason for referral to a rheumatologist is a young female patient with arthralgias from whom the referring physician has obtained a blood sample testing positive for anti-nuclear antibody (ANA). Studies of patients with Graves' disease and chronic autoimmune thyroiditis have demonstrated upward of 26% positivity for ANA and 34% for anti–single-stranded DNA antibodies. No patients in these studies had antibodies to double-stranded DNA or extractable nuclear antigens (anti-Ro/SS-A, anti-La/SS-B, anti-SM, or anti-RNP).[100] With respect to polymyalgia rheumatica and giant cell arthritis, few studies are available, with some demonstrating a relationship[101] but most reporting no association.[102,103] However, the occurrence of polymyalgia rheumatica or giant cell arthritis may be more common in patients with autoimmune thyroid disease.[104] In people with fibromyalgia, an attenuated response of TSH to thyrotropin-releasing hormone, as well as an increased prevalence of anti-thyroid antibodies compared with control subjects, has been reported (the clinical significance of which is unknown).[105,106]

## Rheumatoid Arthritis and Psoriatic Arthritis

In both RA and psoriatic arthritis, an increase in subclinical and clinical disease and an increase in the frequency of anti-thyroid antibodies has been demonstrated compared with control subjects.[107-109] Even though this increase in anti-TPO and anti-TG antibodies and abnormal variation in TSH level was demonstrated, no significant alteration of hormone levels was found, nor was there any association with any particular RA phenotype.[110]

## Sjögren's Syndrome

Prevalence of thyroid disease runs from a low of 10% to a high of 70%; however, this phenomenon may be related to the demographics of Sjögren's syndrome, which usually affects older women. In one study, the occurrence of hypothyroidism was 14%, with the occurrence of thyrotoxicosis being 1.8%.[111] Symptoms of Sjögren's syndrome, such as conjunctivitis sicca and xerostomia, have been reported in up to 32% of patients with autoimmune thyroiditis.[112] In a large study of 479 patients with Sjögren's syndrome, the frequency of HT (6.26%) was found to be higher than in the normal population (1% to 2%); however, this increased frequency was not seen for Graves' disease. It was also observed that the presence of Graves' disease and HT could appear either before or after the occurrence of Sjögren's syndrome, making it difficult to ascertain if primary Sjögren's syndrome was a predisposing factor for the development of autoimmune thyroiditis.[113]

## Scleroderma and Mixed Connective Tissue Disease

As previously discussed, fibrosis of the gland can lead to hypothyroidism, and in this group only 50% of patients had positive tests for anti-thyroid antibodies.[114] Unfortunately, few data are available for mixed connective tissue disease. Anti-thyroid antibodies were found in a quarter of the

patients, and overt hypothyroidism was found in fewer than 20% of patients.[109]

### Juvenile Idiopathic Arthritis

The occurrence of anti-thyroid antibodies (anti-TG and anti-TPO), as well as thyroid function, was assessed in a small group of children with juvenile idiopathic arthritis (JIA) compared with control subjects. The investigators concluded that children with JIA have a higher incidence of anti-thyroid antibodies and subclinical hypothyroidism than do normal children. The children who were positive for antibodies all had oligoarticular JIA.[115]

### Spondyloarthritis

To evaluate the prevalence of HT in a group of patients ($n$ = 357) with spondyloarthritis (SpA) and normal age-matched control subjects ($n$ = 318), serum levels of TSH, free triiodothyronine, and free thyroxine, along with titers of anti-TG and anti-TPO antibodies, were assayed.[116] Indices of thyroid autoimmunity were significantly more frequent in patients with SpA than in control subjects (24.1% vs. 10.7%, $P$ <0.05). In the SpA group, a higher prevalence of HT was found in patients with active disease than in those with low to moderate disease levels. Also in the SpA group, patients with a disease duration greater than 2 years had a higher prevalence of HT and anti-TPO antibody positivity than did patients with a disease duration less than 2 years. Ultrasonography of the thyroid gland was performed in all subjects, and rheumatic activity was evaluated. Ultrasonography detected a significantly higher frequency of thyroid nodules and hypoechoic pattern in patients with SpA than in control subjects. HT and anti-TPO antibodies were significantly more frequent in patients with SpA who had peripheral involvement (68.6%) than in patients with axial involvement (31.4%; $P$ <0.05). This study demonstrated a significantly higher prevalence of thyroid autoimmunity in patients with SpA compared with control subjects. Thyroiditis occurs more frequently in patients with longer disease duration and active rheumatic disease. The authors suggested that thyroid function tests be part of the clinical evaluation in patients with SpA.[116]

### Hashimoto's Thyroiditis

HT frequently overlaps with autoimmune disease. To evaluate for the prevalence of various non–organ-specific autoantibodies in patients with HT, 80 patients with SLE and RA and a control group of 34 healthy subjects were examined for serum FT3 and FT4, TSH, and antibodies against thyroglobulin and thyroperoxidase; in addition, ultrasound of the thyroid gland was performed.[117] Patients with HT had a significantly higher prevalence of ANAs than did control subjects (45% vs. 14.7%, $P$ <0.001). There were no significant differences in the prevalence of other antibodies between the groups. $ANA^+$ patients were younger than $ANA^-$ patients and had significantly higher anti-TG values ($P$ <0.05). The prevalence of HT in people with RA and SLE was significantly higher than in the control subjects (24% vs. 8%, $P$ <0.05). No significant differences in the prevalence of HT were detected between patients with SLE and RA. The investigators concluded that ANA is the most frequent non–organ-specific antibody associated with HT, whereas the other antibodies occur rarely. The prevalence of HT in patients with SLE and RA was 24%. These results indicate that it is clinically important to screen patients with SLE and RA for the coexistence of thyroid autoimmune disease.[117]

## HYPOPARATHYROIDISM

A disorder of PTH is usually caused by either autoimmune destruction of the parathyroid glands (isolated endocrine deficiency syndrome or failure of other endocrine glands) or neck surgery with extensive removal of parathyroid tissue. Two other lesser causes are a congenital disorder with failure of derivatives of the third and fourth pharyngeal pouch (DiGeorge syndrome) and intra-cellular processing defects or mutations of the calcium sensing receptor. Bone structure and bone turnover is different from normal and may result in enthesopathy, as well as paravertebral and or subcutaneous calcifications.[118] The clinical manifestations (circumoral numbness, paresthesias, carpal and pedal muscle spasms, laryngeal spasm, tetany, and/or seizures), which are seen infrequently, are a result of hypocalcemia.

Albright's osteodystrophy or pseudo-hypoparathyroidism (pseudo HoPT) results from end organ resistance (bone and kidney) to PTH and presents with elevated levels of PTH, hypocalcemia, and hyperphosphatemia. Type 1a HoPT (autosomal dominant) is inherited maternally and characterized by calcification of the paraspinal ligaments, short stature, and mental retardation. Patients clinically have shortened metatarsal and metacarpal bones and a defect in the genes encoding the α-subunit of the cell membrane–associated guanine nucleotide stimulating unit of adenyl cyclase.[119] Type 1b HoPT also has resistance to PTH but has a normal phenotype and is inherited paternally.[120,121] Soft tissue calcifications not clinically relevant (in basal ganglia, cataracts, shoulder joints, or subcutaneous tissues of the hands) have been reported in HoPT and infrequently in pseudo HoPT.[122] Surgically induced HoPT may also be accompanied by muscle weakness that is usually related to the degree of hypocalcemia and is responsive to treatment with vitamin D and calcium.

Renal disease can result in crystal deposition disease (sodium urate, calcium pyrophosphate, or basic calcium phosphate hydroxyapatite) as a result of hyperphosphatemia from reduced glomerular filtration and secondary hyperparathyroidism.[123] Sodium urate deposition results in acute gout seen more commonly in people with renal insufficiency. Gout is rare in patients undergoing dialysis but can be seen after renal transplantation with decreased creatinine clearance and use of calcineurin inhibitors, such as cyclosporine. CPPD deposition is seen less often in renal disease than gout or hydroxyapatite and is rare in individuals undergoing dialysis. Hydroxyapatite deposition can cause acute synovitis and periarticular inflammation. Painful subcutaneous nodules or chronic asymptomatic nodules (uremic humoral calcinosis) can occur. Prevention is achieved through phosphate restriction, adequate dialysis, and oral phosphate binding agents.

Renal osteodystrophy is a result of osteomalacia, osteitis fibrosa cystica, osteosclerosis, aluminum toxicity, osteoporosis, and β2 microglobulin amyloid deposition and presents with bone pain, muscle wasting, and myalgias, as well as bone fractures.[124] To define the abnormalities in skeletal microstructure and to establish the potential efficacy of PTH replacement in hypoparathyroidism, standard histomorphometric and micro–computed tomography analyses were performed on iliac crest bone biopsies obtained from patients with hypoparathyroidism. Participants were treated with teriparatide for 2 years and compared with age- and sex-matched control subjects with no abnormalities in parathyroid function. Initially bone density was increased and skeletal features reflected the low turnover state with greater bone volume/trabecular bone volume), trabecular width, and cortical width, as well as suppressed mineralizing surface and bone formation rate compared with control subjects. With teriparatide therapy, bone turnover and BMD increased in the lumbar spine. Requirements for calcium and vitamin D fell, whereas serum and urinary calcium concentrations did not change. The investigators concluded that the abnormal microstructure of the skeleton in hypoparathyroidism reflects the absence of PTH. Replacement therapy with PTH has the potential to correct these abnormalities and to reduce the requirements for calcium and vitamin D.[125]

### Similarities to Other Rheumatic Diseases

The skeletal abnormalities of hypoparathyroidism are caused by calcification, which can simulate ankylosing spondylitis with clinical signs, including morning stiffness, gait, and posture.[126] Sacroiliitis is not expected, although it is the earliest manifestation in most patients with ankylosing spondylitis. The patterns of syndesmophytes in patients with hypoparathyroidism can resemble those of ankylosing spondylitis with origin from the vertebral margin and preserved disk space, but more often there is also involvement of the posterior paraspinal ligament. Spinal changes in hypoparathyroidism have also been described to be similar to those in DISH, which is characterized by ossification of the anterior longitudinal ligament of the spine and of various extraspinal ligaments, but is rarely reported before 50 years of age. The pain is not responsive to immunosuppressive agents and NSAIDs but may resolve completely upon treatment with calcitriol.[127] Serum calcium may need to be included in the diagnostic workup of patients with inflammatory back pain, especially if they present with atypical features as previously described. It is important to differentiate hypoparathyroid-related spondylitis from ankylosing spondylitis because the management for the two disorders is different. In fact, some of the drugs used for ankylosing spondylitis, such as bisphosphonates, may worsen hypocalcemia. The mechanism underlying these skeletal changes in hypoparathyroidism is not well defined. Decreased intestinal calcium absorption caused by a defect in the action of 1,25-dihydroxyvitamin D has been suggested to play a role in a controlled study of paravertebral ligamentous ossification.[128] Okazaki and colleagues[129] suggested that the ossifying diathesis of paravertebral ligaments, which is the origin of DISH, might be initiated or aggravated by hypoparathyroidism.

### Systemic Lupus Erythematosus

SLE is known to potentially affect any organ system, and hypoparathyroidism has been found to occur in 4.0% to 5.7% of patients with SLE compared with 1.0% in the general population.[130] Hypoparathyroidism is underestimated because it is poorly manifested clinically and can be precipitated by certain aggravating factors, such as corticosteroid treatment or vitamin D deficiency. Although acute hypocalcemia typically gives symptoms and signs of musculoskeletal irritability, chronic hypocalcemia usually gives mild symptoms and can even be asymptomatic. Despite the possible lack of outward manifestations, hypocalcemia may be a significant health risk as a result of QT interval prolongation and the consequent risk of sudden death. These cases raise the question of whether periodic calcium and phosphate screening should be routine care for patients with SLE.[131]

## HYPERPARATHYROIDISM

PTH along with vitamin D and calcitonin controls calcium homeostasis. These hormones are responsible for bone metabolism and remodeling in addition to maintaining serum calcium in a very narrow range. In primary hyperparathyroidism (HPT), this balance is altered as a result of changes in the parathyroid gland, whereas changes in other organs of the body that result in calcium loss and vitamin D deficiency with increased secretion of PTH are called secondary HPT.[132]

Approximately 1% to 2% of the population has hypercalcemia, with 10% to 20% of these individuals having HPT.[133] Most patients with HPT have a single adenoma; carcinoma is rare, and in secondary HPT, diffuse hyperplasia related to hypocalcemia or resistance to PTH is seen. Secondary HPT is most commonly the result of osteomalacia, vitamin D deficiency, and renal failure.[123] Skeletal symptoms include arthralgias, as well as radiographic findings such as osteitis fibrosa cystica and subperiosteal resorption along the radial side of the phalanges. In addition, the distal tufts of the phalanges may also reveal subperiosteal resorption.

Arthritis associated with HPT involves the small joints of the hand (possibly becoming erosive) and spares the PIP joints. In this respect, it can mimic RA, but the presence of subperiosteal resorption is very distinctive. In contrast to RA, these patients generally have low erythrocyte sedimentation rates, negative rheumatoid factors and anti-citrullinated protein antibodies, and laboratory values consistent with HPT.[134] HPT more commonly involves the radiocarpal, inferior radioulnar, and MCP joints compared with RA. Lytic lesions resulting from HPT in the skeleton (Brown's tumors) are localized areas of fibrous tissue resulting from increased osteoclastic activity, giant cells, and decomposing blood.[135] CPPD (pseudo gout or chondrocalcinosis) is also associated with HPT.[136] Attacks of gout also can be seen in HPT, and the concomitant occurrence of uric acid and CPPD crystals can be found in synovial fluid aspirated from acutely inflamed joints. In addition to the acute attacks of CPPD, chronic CPPD disease may result in erosive disease.[137] Muscle involvement can occur in HPT, presenting with proximal muscle weakness. Muscle enzymes are not

elevated, and both EMG studies and muscle biopsy results demonstrate a picture of denervation.

CHAPTER 123

# Musculoskeletal Syndromes in Malignancy

Samera Vaseer • Eliza F. Chakravarty

**KEY POINTS**

- Musculoskeletal and rheumatic syndromes can be the first presentation of an underlying malignancy. Older age at onset, prominent constitutional symptoms, atypical features of rheumatic disease, and limited response to glucocorticoids or other conventional therapy suggests of a paraneoplastic process.
- Data from numerous cohorts have confirmed a threefold increase in the incidence of malignancy associated with dermatomyositis, including clinically amyopathic dermatomyositis and, to a lesser extent, polymyositis. Risk factors include age greater than 45 years, male gender, rapid onset, rapid weight loss, cutaneous necrosis, high erythrocyte sedimentation rate/C-reactive protein, dysphagia, anti–p155-140 (anti-transcriptional intermediary factor-1γ) antibody, and anti-NXP2 (anti-MJ) antibody.
- Chronic autoimmune conditions including Sjögren's syndrome, rheumatoid arthritis, and systemic lupus erythematosus are associated with an increased risk of lymphoid malignancies compared with the general population. This increased risk is believed to be attributed, at least in part, to chronic inflammation and immune stimulation.
- Patients with systemic sclerosis are at increased risk for developing solid organ tumors that primarily involve tissues affected by the fibrotic process. Positivity for anti-RNA polymerase III confers higher odds for developing cancer within 36 months of systemic sclerosis onset compared with individuals who do not have this antibody.

Musculoskeletal syndromes may be associated with malignancy in a variety of ways, although cause and effect may be difficult to define clearly in many situations. Certain chronic rheumatic diseases have been associated with an increased risk of the subsequent development of malignancy; one example is the development of lymphoma in an individual with primary Sjögren's syndrome. The converse situation also exists, in that certain rheumatic diseases are seen more frequently in the presence of an underlying malignancy, such as dermatomyositis (DM). Little is understood regarding the pathogenesis of connective tissue disease in association with neoplastic disease. Other factors can contribute to the association of musculoskeletal syndromes and malignancy; for example, many of the medications used to treat rheumatic diseases modulate the immune system and may be associated directly or indirectly with an increased risk for the development of malignancy. In unusual circumstances, musculoskeletal involvement occurs as a paraneoplastic process, defined as a hormonal, neurologic, hematologic, or biochemical disturbance that is associated with malignancy but is not directly related to invasion by the neoplasm or its metastases.[1]

## PARANEOPLASTIC SYNDROMES

Musculoskeletal syndromes can develop as a manifestation of a paraneoplastic process and occasionally can be the first presentation of an underlying malignancy. Hematologic malignancies, lymphoproliferative disorders, and solid tumors are associated with a wide variety of paraneoplastic rheumatic syndromes. Older age at onset, atypical features of rheumatic disease, and absence of response to glucocorticoids or other conventional therapy may suggest a paraneoplastic process. Knowledge of the associations with rheumatic syndromes and underlying malignancy is crucial when caring for these patients. Hypertrophic osteoarthropathy, amyloidosis, and secondary gout are reviewed in Chapters 87, 93, and 106. Table 123-1 lists common paraneoplastic associations.

### Carcinomatous Polyarthritis

The term *carcinomatous polyarthritis* is used to describe the development of arthritis in association with malignancy, but it is distinct from arthritis associated with metastasis or direct tumor invasion. Table 123-2 lists common features of carcinomatous polyarthritis. This disease generally occurs in patients who are older than 50 years, has an explosive onset, and often develops in close temporal correlation with the discovery of the malignancy. Although it can have various presentations and may mimic the appearance of rheumatoid arthritis (RA)[2] or asymptomatic migratory polyarthritis,[3] carcinomatous polyarthritis is more often a seronegative asymmetric disease with predominant involvement of the lower extremities and some sparing of the small joints of the hands. There is no evidence of direct tumor extension or metastasis and no specific identifying histologic or radiographic appearance. Carcinomatous polyarthritis can occur in association with many types of malignancy, but it has been reported most frequently in association with breast, colon, lung, and ovarian cancers and with lymphoproliferative disorders.[4] The underlying pathogenesis of this process has not been elucidated; however, the arthritic symptoms may be improved with successful treatment of the malignancy.[5]

**TABLE 123-1** Paraneoplastic Syndromes

| Connective Tissue Disease | Malignancy | Clinical Setting | Clinical Alert |
|---|---|---|---|
| Carcinomatous polyarthritis | Multiple types of solid tumors, including breast; lymphoproliferative disorders | See Table 123-2 | See Table 123-2 |
| Vasculitis | Lymphopoietic and hematopoietic malignancies | Cutaneous vasculitis most common; systemic vasculitis rare | Vasculitis not related to infections, medications, or autoimmune disease |
| Mixed cryoglobulinemia | Non-Hodgkin's lymphoma | Immune complex–mediated disease with cutaneous vasculitis, neuropathy, fatigue, and visceral organ involvement | Usually appears 5-10 yr after diagnosis of cryoglobulinemia |
| Panniculitis | Hematologic malignancies; pancreatic, breast, and prostate cancers | Induration of skin and deeper tissues; eosinophilia often present | Usually refractory to prednisone |
| Fasciitis | Ovarian, breast, gastric, and pancreatic cancers | Palmar fasciitis with inflammatory polyarthritis; similar in presentation to reflex sympathetic dystrophy | Bilateral presentation; severe fibrosis and contractures; aggressive course |
| Reflex sympathetic dystrophy syndrome | Multiple cancer types; Pancoast tumors | Tumors may invade stellate ganglionar brachial plexus on affected side | Absence of typical antecedent factors; failure to respond to conventional therapies |
| Erythromelalgia | Myeloproliferative disorders | Often seen in setting of thrombocytosis | — |
| Atypical polymyalgia rheumatica | Renal, lung, and colon cancer; multiple myeloma | — | Age <50 yr; asymmetric involvement; poor response to prednisone |
| Digital necrosis | Gastrointestinal and pulmonary tumors | Severe Raynaud's phenomenon with onset after age 50 yr | Asymmetric features; digital necrosis |
| Remitting seronegative symmetric synovitis with pitting edema | Several tumor types | Abrupt onset of arthritis and edema surrounding wrists and small joints of hands | Presence of fever, weight loss; poor response to prednisone |
| Multicentric reticulohistiocytosis | Lung, stomach, breast, cervix, colon, and ovarian carcinomas | — | — |
| Lupus-like syndromes | Variety of solid tumors and lymphoproliferative disorders | — | Rare associations with malignancy limited to case reports |
| Anti-phospholipid antibodies | Multiple cancer types | Association between antibodies, cancer, and risk of thrombosis unclear | Higher presence of antibodies found in patients with malignancy |
| Osteogenic osteomalacia | Solid tumors and tumors of mesenchymal origin | Bone pain and muscle weakness | Diligent search is indicated in all patients with late-onset apparent idiopathic osteomalacia |
| Sarcoidosis | Cervical, bladder, gastric, lung, breast, and renal cancers and cutaneous and pulmonary squamous cell carcinomas | Highest incidence of "malignancy" during first 4 yr after detection of granulomas | Malignant tumors can cause sarcoid-like tissue reactions leading to mistaken diagnosis of sarcoidosis before recognition of malignancy |
| Lymphomatoid granulomatosis | Lymphoma | Unusual granulomatous form of vasculitis with angiodestructive infiltration of various tissues | — |

## Vasculitis

Vasculitis in association with malignancy is uncommon and has a reported prevalence of only 8% in patients with a malignancy.[6] The association seems to be significantly higher with lymphoproliferative and myeloproliferative disorders than with solid tumors, and vasculitis commonly predates the identification of malignancy. The vasculitic process usually affects small vessels and is cutaneous and only rarely involves significant organs. Up to 5% of patients with cutaneous vasculitis have an underlying neoplasm.[7,8] Treatment often requires the use of glucocorticoids in addition to therapy directed against the underlying malignancy.

Table 123-1 shows malignancies associated with vasculitis. In the setting of malignancy, it is believed that persistent antigen stimulation from the tumor results in T cell activation or immune complex formation and deposition.

The development of small vessel vasculitis has been reported to ante-date and post-date the development of lymphoproliferative and myeloproliferative diseases. One group of investigators retrospectively examined the cases of 421 adult patients with cutaneous vasculitis and identified 16 in whom an associated malignancy had developed.[8] Of these 16 patients, 9 had hematologic neoplasia and 7 had malignant solid tumors. Similar findings were reported by

**TABLE 123-2** Features of Carcinomatous Polyarthritis

| Nonspecific histopathologic appearance of synovial lining |
| No periosteal reaction |

investigators who found an underlying malignancy in 8 of 192 patients with cutaneous vasculitis. Most malignancies (six of eight) were hematologic, and five of eight pre-dated the diagnosis of cancer.[9] In a retrospective analysis of 23 patients with cutaneous vasculitis and hematologic malignancies, the authors were able to attribute the presence of vasculitis to the malignancy itself in 61% of cases.[10]

Systemic vasculitis is much less commonly associated with underlying malignancy. In case reports and small series it has been reported that anti-neutrophil cytoplasmic antibody (ANCA)$^-$ and ANCA$^+$ vasculitis is associated with hematologic malignancies.[11-13] Granulomatosis with polyangiitis likewise has been associated with the development of several types of malignancies, including lymphoproliferative disorders, bladder cancer, and renal cell carcinoma.[14,15] In some cases the malignancy was diagnosed within months of the diagnosis of granulomatosis with polyangiitis,[14] and in other reports, cancer developed many years after diagnosis and treatment of vasculitis,[15] and thus it is unclear whether the malignancies were a result of the vasculitis or possibly of the treatment. A group of investigators from the Cleveland Clinic published a retrospective study of the temporal relationship between vasculitis and cancer.[16] During an 18-year study period, the investigators found only 12 cases of vasculitis and cancer diagnosed within the same 12-month period: Six patients had lymphoproliferative disorders, and six had solid tumors. In most cases, the vasculitis responded partially to immunosuppressive therapy, but the investigators observed a more impressive improvement of vasculitis with definitive treatment for the underlying malignancy. In a more recent study, investigators found 20 cases of malignancy among 200 patients with ANCA$^+$ vasculitis; 6 malignancies were diagnosed concurrently with diagnosis of vasculitis, and 14 malignancies pre-dated vasculitis by a median of 96 months.[17] Only 4 of 20 malignancies in this series were lymphoproliferative; the others were solid organ tumors.

Vasculitis associated with underlying malignancy often responds poorly to conventional therapy directed against the vasculitis. In one series of 13 patients with cutaneous vasculitis and lymphoproliferative or myeloproliferative disorders, symptoms of vasculitis had a poor response to therapy with NSAIDs, glucocorticoids, antihistamines, and antiserotonin agents. Although the investigators reported a lessening of the severity of the vasculitis after chemotherapy was directed against the malignancy, they generally found chemotherapy to be ineffective. Of the 13 patients identified, 10 died as a direct result of the malignancy.[18] Similarly, Hutson and Hoffman[16] found a general concurrence between improvement in vasculitic syndrome and definitive treatment for the associated underlying malignancy. More recently, in a study of cutaneous small-vessel vasculitis associated with solid tumors (most commonly lung, breast, and prostate), investigators found a significant response to immunosuppressive therapy directed against the vasculitis, although concurrent treatments for the underlying malignancy were undertaken.[19]

## Cryoglobulinema

Cryoglobulins are immunoglobulins that precipitate at a reduced temperature. Cryoglobulinemia manifests with symptoms of hyperviscosity or vasculitis. Patients often present with fatigue, arthralgia or arthritis, cutaneous vasculitis or purpura, neuropathy, digital ischemia, and visceral organ involvement (renal or pulmonary).[20] The following three types of cryoglobulins have been identified:

- *Type I:* Monoclonal Ig, either IgG or IgM; this type is associated with lymphoproliferative disorders.
- *Type II:* Monoclonal IgM directed against polyclonal IgG; type II cryoglobulins were initially thought to be idiopathic and were known as mixed essential cryoglobulinemia. With the identification of hepatitis C virus (HCV), it has been discovered that most of these patients have HCV infection that is directly involved in the pathogenesis of the cryoglobulins. Specific epitopes of HCV antigens are recognized by IgG components of immune complexes, and viral particles are found in the cryoprecipate.[21] In one study, investigators found clonal B cell populations in the peripheral blood of 48% of HCV$^+$ patients with type II cryoglobulinemia, many of whom were eventually diagnosed with a B cell malignancy.[22] Overall, it is estimated that non-Hodgkin's lymphoma may develop in approximately 5% to 8% of patients who have mixed cryoglobulinemia, usually after 5 to 10 years of the diagnosis of cryoglobulinemia.[23,24] The risk of developing non-Hodgkin's lymphoma among patients with HCV$^+$ cryoglobulinemia may be 35 times higher than that in the general population.[25] Other data suggest that HCV infection may be associated with other hematologic malignancies.[26,27] At this time, the subset of patients with mixed cryoglobulinemia in whom lymphoma will develop cannot be predicted.
- *Type III:* Mixed polyclonal IgG and IgM; type III cryoglobulins are commonly seen with a variety of illnesses, including connective tissue diseases (systemic lupus erythematosus [SLE] and RA) and infections. In one study of 607 patients diagnosed with mixed cryoglobulinemia, 27 cases of hematologic malignancies were identified. Of these, systemic autoimmune diseases were detected in 56% of the cases of non-Hodgkin's lymphoma.[27]

## Panniculitis

Fasciitis-panniculitis syndrome, which includes eosinophilic fasciitis, is characterized by swelling and induration of the skin that extends into deeper subcutaneous tissues

and is associated with fibrosis and chronic inflammation. Patients may experience arthritis and subcutaneous nodules similar to those seen in people with erythema nodosum. The arthropathy seems to be secondary to periarticular fat necrosis, can be monarticular or polyarticular,[28] and may mimic RA. This syndrome can be idiopathic and have a benign course, or it can be secondary to a variety of infectious, vascular, or traumatic etiologies. Subcutaneous panniculitis-like T cell lymphoma, derived from a/b T cells, is considered a primary cutaneous T cell lymphoma, with biopsy required to distinguish it from autoimmune panniculitis.[29] In a few patients, the fasciitis-panniculitis syndrome is associated with an underlying malignancy. Hematologic malignancies are most often associated with this syndrome and are usually diagnosed concurrently or within the first year.[30,31] Pancreatic cancer and pancreatitis also can be associated with this syndrome.[28] Patients with cancer-associated fasciitis-panniculitis syndrome are predominantly female and generally have a refractory response to prednisone.[30]

## Palmar Fasciitis

Palmar fasciitis and arthritis is a syndrome characterized by progressive bilateral contractures of the digits, fibrosis of palmar fascia, and inflammatory polyarthritis.[32-34] The metacarpophalangeal and proximal interphalangeal joints are most commonly affected; other affected joints include the elbows, wrists, knees, ankles, and feet. Indurated reticulate palmar erythema also can be seen as part of the palmar fasciitis spectrum.[35] Palmar fasciitis is almost uniformly associated with the presence of an underlying malignancy, most often ovarian, breast, gastric, and pancreatic tumors.[33,34,36,37] Although initially thought to be an atypical variant of reflex sympathetic dystrophy, the severity of manifestations, bilateral presentation, and strong association with occult malignancy suggest that, in these cases, palmar fasciitis is a distinct entity that behaves as a paraneoplastic syndrome (Figure 123-1). Neither glucocorticoids nor chemotherapy appear to result in significant improvement, although fasciitis occasionally regresses with treatment of the underlying malignancy.[32]

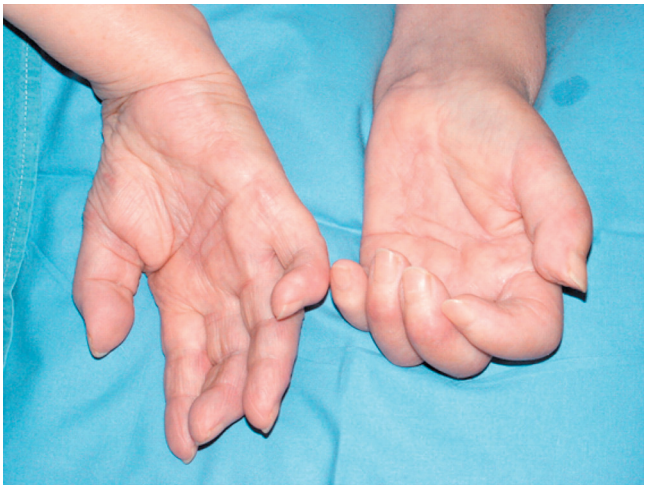

**Figure 123-1** Palmar fasciitis and polyarthritis as a paraneoplastic syndrome associated with tubal carcinoma in a 73-year-old woman. *(From Denschlag D, Riener E, Vaith P, et al: Palmar fasciitis and polyarthritis as a paraneoplastic syndrome associated with tubal carcinoma: a case report.* Ann Rheum Dis *63:1177–1178, 2004.)*

## Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy (complex regional pain syndrome) and a variant, shoulder-hand syndrome, are characterized by regional pain, swelling, vasomotor instability, and focal osteoporosis in a given limb; this condition is thought to be caused by sympathetic dysfunction. The absence of associated antecedent factors such as stroke, myocardial infarction, or trauma and failure to respond to conventional therapy may warrant a search for an underlying malignancy. A variety of malignancies have been associated with the development of reflex sympathetic dystrophy or its variants.[38,39] Pancoast tumor of the lung apices or other malignancies that infiltrate the stellate ganglion or brachial plexus have been described in patients with reflex sympathetic dystrophy.[40-42] Therapy directed against the underlying malignancy may lead to some amelioration of symptoms.

## Erythromelalgia

Erythromelalgia is an enigmatic condition characterized by attacks of severe burning, erythema, and warmth of the extremities, with symptoms predominantly involving the feet.[43,44] Symptoms are often exacerbated when the extremities are placed in a dependent position, during ambulation, or during exposure to increased temperatures. Partial relief can be obtained through elevation or cooling of the extremity. This disorder can occur idiopathically (60%) or secondary to another disease (40%).[43,45] Myeloproliferative disorders, including polycythemia vera and essential thrombocytosis, are common primary causes and have been found to precede the diagnosis of erythromelalgia by several years.[7,44,46] The underlying pathophysiology of erythromelalgia remains unknown; however, it is often associated with thrombocythemia. In the largest published retrospective cohort, 168 patients at the Mayo Clinic were identified with this diagnosis between 1970 and 1994.[47] Investigators found that after a mean follow-up of 8.7 years, 31.9% of patients reported worsening of disease, 26.6% reported no change, 30.9% reported improvement, and 10.6% reported complete resolution of symptoms. Kaplan-Meier survival curves revealed a significant decrease in survival compared with control subjects. A history of myeloproliferative disease was found in 15 of 168 patients. The exact cause of the symptoms is unclear, but microvascular arteriovenous shunting has been hypothesized.[48] In cases of secondary erythromelalgia, platelet breakdown products and platelet microthrombi may underlie disease pathogenesis.[7] The most effective therapy seems to be the use of daily aspirin, leading to a significant relief of symptoms. A host of other therapies have been tried with varying success.[49] Because of the association with myeloproliferative diseases, routine monitoring with complete blood cell counts is prudent.

## Polymyalgia Rheumatica

Polymyalgia rheumatica, a disorder affecting older adults, manifests with discomfort and stiffness in the shoulder and

hip girdle, fatigue, anemia of chronic disease, and elevated erythrocyte sedimentation rate (ESR). Classically this condition responds to moderate doses of prednisone within 48 hours. A variety of other conditions can have presentations that mimic polymyalgia rheumatica, including other rheumatic disorders, systemic infections, and malignancy.[50] Although the association between polymyalgia rheumatica and malignancy has been controversial, atypical features of polymyalgia rheumatica may suggest the presence of occult malignancy, including age younger than 50 years, limited or asymmetric involvement of typical sites, ESR less than 40 mm/hour or greater than 100 mm/hour, severe anemia, proteinuria, and poor or delayed response to 20 mg of prednisone daily. Kidney, lung, and colon cancer and multiple myeloma are most often found in patients presenting with atypical polymyalgia rheumatica.[51-53] In one study of patients undergoing evaluation for possible polymyalgia rheumatica, it was found that 10% had a diagnosis of malignant neoplasms.[54] In contrast, several prospective studies have shown that patients presenting with classic polymyalgia rheumatica or giant cell (also known as temporal) arteritis do not have an increased risk of the development of malignancy compared with age-matched control subjects.[55-59]

## Raynaud's Phenomenon and Digital Necrosis

The development of digital necrosis or profound Raynaud's phenomenon may suggest the presence of infection, inflammatory disease, or an underlying malignancy. In patients older than 50 years, the development of Raynaud's phenomenon, particularly in an asymmetric fashion or in association with digital necrosis, should raise the possibility of a paraneoplastic process. In one study, underlying malignancy was associated with digital ulcers in 15% of patients presenting with digital ischemia.[60] These features often antedate the diagnosis of the malignancy by an average of 7 to 9 months.[61,62] A variety of solid tumors and lymphoproliferative disorders have been associated with this syndrome.[61-67] Certainly, the presence of digital necrosis in patients with DM is highly suggestive of the presence of an underlying malignancy. Mechanisms proposed include cryoglobulinemia, immune complex–induced vasospasm, hypercoagulability, marantic endocarditis with emboli, and necrotizing vasculitis.[67] Therapy with interferon-α also has been reported in association with the development of Raynaud's phenomenon and digital necrosis.[68-70]

## Remitting Seronegative Symmetric Synovitis with Pitting Edema

Remitting seronegative symmetric synovitis with pitting edema is an uncommon disorder primarily affecting the metacarpophalangeal joints and the wrists. Although the underlying cause and pathogenesis are unclear, lymphoma, myelodysplastic syndrome, and several solid tumors, mostly adenocarcinoma, all have been reported in association with this illness.[71-75] In one retrospective study from a single center in the United States, it was found that cancer developed in 3 of 14 patients who had remitting seronegative symmetric synovitis with pitting edema.[76] Characteristics that suggest possible underlying malignancy include the presence of systemic features, such as fever or weight loss, and a poor response to glucocorticoids.[73,74]

## Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis is a rare condition characterized by the presence of cutaneous papules. This condition is often associated with a destructive arthritis of the interphalangeal joints of the hands. The papules are flesh colored to brown-yellow and classically are present in the periungual region and on the dorsal aspect of the hands and face. Arthritis mutilans may develop in 50% of cases. The characteristic histologic appearance of tissue infiltration with histiocytes and multinucleated giant cells can be found in affected skin, joints, and occasionally internal organs.[77] Multicentric reticulohistiocytosis has been reported in association with hyperlipidemia, malignancies, and autoimmune diseases. Malignancy has been associated in 25% to 31% of cases, although most literature consists of individual case reports.[78,79] The most frequently seen malignancies include carcinoma of the lung, stomach, breast, cervix, colon, and ovary.[78]

## Lupus-like Syndromes

Lupus-like syndromes are rarely associated with underlying malignancy. Isolated case reports have described lupus-like syndromes with ovarian carcinoma[80,81] and hairy cell leukemia[82]; subacute cutaneous lupus was reported in a patient with breast carcinoma.[83] Studies of the presence of antinuclear antibodies (ANAs) in patients with cancer have yielded mixed results. In two studies, investigators were unable to find a significantly increased prevalence of ANAs in patients with solid tumors or lymphomas compared with healthy control subjects.[84,85] In contrast, in a smaller study, investigators found an increased prevalence in patients with non-Hodgkin's lymphoma compared with control subjects (21% versus 0),[86] and in another study, investigators found a 27.7% prevalence of ANAs in 274 patients with various malignancies compared with a prevalence of 6.45% in 140 healthy control subjects.[87] There do not seem to be any predictive features that suggest occult malignancy in patients presenting with lupus-like syndromes or positive ANAs.

## Anti-phospholipid Antibody Syndrome

Anti-phospholipid antibodies (aPLs) and their association with thromboses have been described as a primary syndrome and a secondary phenomenon in autoimmune diseases, primarily SLE. More recently, aPLs have been associated with a variety of malignancies. Correlations between aPLs in individuals with cancer and thromboembolic events have been less clear, however.

Several studies have shown the presence of aPLs in patients with solid tumors and lymphoproliferative disorders at a higher frequency than the 1% to 5% seen in the general population.[88,89] In an early study of 216 consecutive patients with cancer, it was found that 22% were positive for anticardiolipin antibodies compared with 3.4% of control subjects. In this study, a twofold increase was found in the development of thromboembolism in patients with positive

antibodies compared with patients who had negative serologies; study findings also indicated that most thromboembolic events occurred in patients with higher antibody titers.[90] Other studies have confirmed the association between malignancy and aPLs (12.5% to 68%) but have been unable to show a correlation with thromboembolic events.[86,88,91-95] A correlation between antibody titer and disease activity has been shown in some studies,[83,85] and decreased survival has been shown in other studies.[95] In a recent survey of 95 patients with cancer who were hospitalized in the intensive care unit, an aPL seropositivity rate of 74% was found; however, autoantibody status was not associated with mortality.[96] Upon a review of the literature, it was concluded that aPLs resolve in one-third of patients with cancer after treatment for the underlying malignancy.[97]

Studies of the prevalence of aPLs in unselected patient populations have shown an association with underlying malignancy. A prospective study in France found that 7% of 1014 consecutive patients admitted to a medical ward had aPLs.[98] In antibody-positive patients, cancer was the most frequently associated disease. In a more recent study in patients presenting with a first ischemic stroke, a significantly higher rate of the development of cancer within 12 months was found in patients who had anti-cardiolipin antibodies compared with patients without these antibodies (19% vs. 5%).[99]

## Osteomalacia

Osteomalacia is the softening of bones that is often associated with the failure of adequate calcification as a result of renal dysfunction or a lack of vitamin D. Osteomalacia has been associated with benign and malignant solid tissue and mesenchymal tumors.[100] Tumors causing oncogenic osteomalacia overproduce fibroblast growth factor 23 (FGF-23), and elevated serum levels of FGF-23 can be detected in patients with this paraneoplastic condition.[101,102] Octreotide scintigraphy may be a useful tool for identifying occult tumors.[103,104] Upon removal of the tumor, there often seems to be resolution of the osteomalacia and normalization of serum FGF-23 levels.[102]

## Sarcoidosis

Noncaseating granulomas can occur in numerous settings and are not pathognomonic for sarcoidosis. Granulomas resembling those of sarcoidosis may be found in lymph nodes that drain sites of malignancy. These tumor-related tissue reactions resulting in granuloma formation have been described with many types of malignant lesions, including solid tumors and lymphomas.[105,106] Because the clinical and radiographic presentation of sarcoidosis can be virtually indistinguishable from cancer, it is important to pursue aggressive evaluation in patients with sarcoidosis.[107,108]

The risk of the development of malignancy in patients with established diagnoses of sarcoidosis is controversial. Some studies have shown an increased risk of the development of lung cancer and lymphoma,[109-111] whereas other studies have shown no increased risk of cancer compared with the general population.[107,112,113]

## Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare disorder with angiodestructive and lymphoproliferative features involving the lung and, less often, the skin and central nervous system. Although lymphocytic infiltration of vessels is a hallmark of the disease, lymphomatoid granulomatosis now seems to fall within the spectrum of lymphoproliferative disorders.[114] Despite the predominance of T cells within inflammatory infiltrates, studies have suggested that an Epstein-Barr virus (EBV)-associated B cell proliferation may underlie the pathogenesis of the disease.[115,116] Prognosis is generally poor, with a median survival from diagnosis of 14 months,[117] although more recent reports suggest some response to rituximab therapy.[118,119] Frank lymphomas evolve in 25% of cases.[120]

## Inflammatory Myopathies

The inflammatory myopathies in adult populations encompass a group of illnesses characterized by an idiopathic immune-mediated attack on skeletal muscle resulting in muscle weakness. An association between myositis and cancer was first proposed in 1916. The association between inflammatory myopathy and cancer is well described in adults, although the pathophysiologic mechanisms underlying the association remain elusive. Many epidemiologic studies substantiate this association, which appears stronger for DM than for other subtypes. Associations between polymyositis (PM) and inclusion body myositis are becoming increasingly recognized. New data have emerged regarding the pathologic changes observed in muscle tissue and cancer. Zampieri et al.[121] hypothesized that in genetically predisposed patients, cancer is accompanied by subclinical tumor-induced myopathy, which can later evolve to full-blown autoimmune myositis. These investigators compared muscle biopsies of 13 patients with myositis, three of them with cancer-associated myositis, 14 with colorectal cancer unrelated to myositis, and 19 healthy control subjects. They found a higher number of fibers with internally located nuclei, a sign of muscle damage, in patients affected with myositis and in those with colorectal cancer, but not in control subjects.[121] These investigators suggest that myositis-specific antigens are expressed in regenerating muscle fibers and trigger an aberrant autoimmune response that acts as a positive feedback loop. These findings are intriguing and require further investigation.[122]

On average, the prevalence of malignancy in association with the inflammatory myopathies has been approximately 15% to 25%, which appears to be consistent across populations studied. However, the frequency of malignancy has ranged from 6% to 60% in patients with DM and from 0 to 28% in patients with PM.[123,124] Other estimates have placed the incidence of cancer in patients with inflammatory myopathies at five to seven times that of the general population.[123]

One of the first large population-based studies was the National Swedish Registry of 788 PM/DM cases. A moderate but significant increase was found in the incidence of cancer in male and female patients with PM. A clear increase in the number of cancers in patients with DM was found, especially in female patients. The risk of cancer was

high during the first 5 years in patients with DM, which strongly suggests its association with cancer. The risk of cancer of the ovary was increased nearly 17-fold.[125] Hill and colleagues[126] studied a pooled cohort of patients from Sweden, Denmark, and Finland and found 198 cases of cancer in 618 patients with DM. The standardized incidence ratio (SIR) for malignancy with DM was 3. Similar results were found in a Scottish cohort of 286 patients with DM.[127] Of patients, 77 were found to have underlying malignancies, with an SIR of 3.3 to 7.7. In a National Australian Registry of 537 myositis cases, increased rates of cancers were found in many phenotypes. Cases were restricted to biopsy-proven myositis. Many type of cancers were seen, but the most frequent were breast and lung cancer (Figure 123-2A and B).[128]

DM has been associated with a wide range of malignancies; interestingly, solid tumors are most often seen in cancer-associated myositis as opposed to lymphoid malignancies. Most common tumor types are ovarian, lung, and gastric tumors in European populations and nasopharyngeal malignancies in Asian populations. All of these studies have suggested that cancers are most commonly diagnosed within 1 to 2 years of diagnosis of DM. In a nationwide Taiwanese study, 9.4% of 1012 patients with DM were found to have an underlying malignancy, the most common of which was nasopharyngeal cancer, followed by lung cancer.[129,130] In a smaller study, 66.6% of 15 patients with DM in Singapore had malignancies, most of which were nasopharyngeal carcinoma.[131] Eight Caucasian patients found to have nasopharyngeal carcinoma within 1 year of diagnosis of DM were reported in Tunisia.[132] A similar study from Japan found that cancer was diagnosed in 24% of patients with DM; the majority had gastric cancer, which is a common malignancy in the Japanese population.[133]

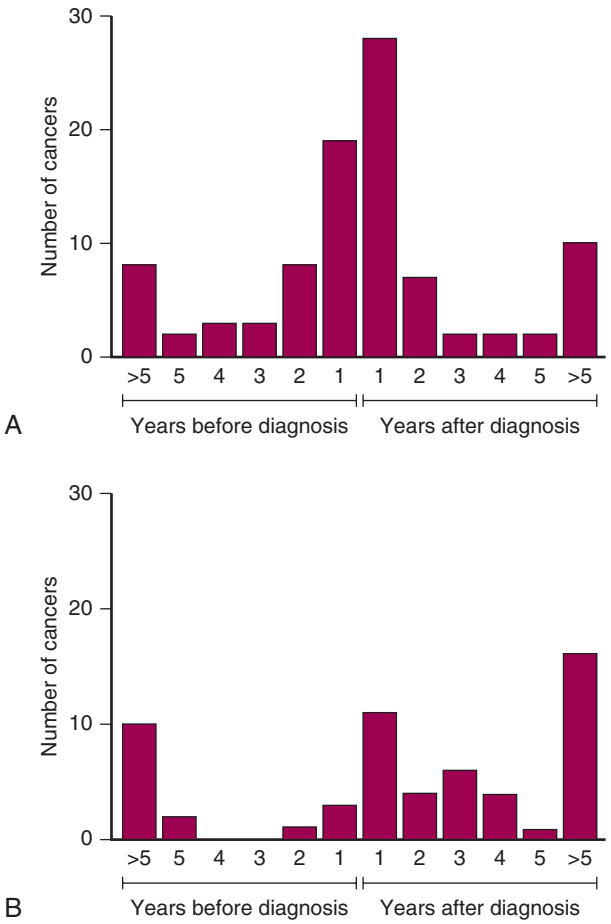

**Figure 123-2** **A,** Temporal relation between the diagnosis of dermatomyositis and the diagnosis of cancer. **B,** Temporal relation between the diagnosis of polymyositis and the diagnosis of cancer. *(From Sigurgeirsson B, Lindelöf B, Edhag O, Allander E: Risk of cancer in patients with dermatomyositis or polymyositis: a population-based study.* N Engl J Med *326:363–367, 1992.)*

In people with PM, the relative risk (RR) of developing internal malignancies seems to be lower than that for people with DM, but it is consistently increased compared with that expected in the general population. Studies have found a 14% to 30% prevalence of cancer among patients with PM, with SIRs increased to 1.2 to 2.1.[126-129] The nationwide Taiwanese study found a 4.4% incidence of cancer among 643 patients with PM, with an SIR of 2.15 compared with the general population.[130] Small numbers of many types of cancers were found in these studies. These studies confirm results found in previous large studies of Swedish and Finnish populations and a 1994 meta-analysis of all published case-control and cohort studies of malignancy and myositis that identified odds ratios for the association of cancer with DM and PM of 4.4 and 2.1, respectively.[134]

In amyopathic DM, a variant of DM in which typical cutaneous manifestations are present with subclinical or no identifiable muscle disease, the association with underlying malignancy is becoming clearer. Whereas earlier reports were limited to small groups of patients,[131,135-137] more recent cohort studies and a systematic review of the amyopathic DM literature have suggested similar associations between amyopathic DM and internal malignancies.[133,138,139]

Far less is known about the association of inclusion body myositis and underlying malignancy. In Buchbinder's study, 52 patients with inclusion body myositis were identified.[128] Of these patients, 12 were found to have internal malignancies, with an SIR of 2.4.

Not all studies concur regarding the association between the inflammatory myopathies and malignancy.[140,141] In a study performed at the Mayo Clinic, patients with myositis did not seem to have a statistically significant risk for the development of malignancy. No clinical differences were seen between patients in whom a malignancy did and did not develop.[141] Despite the negative results of some studies, most work appears to support the notion of an increased risk of malignancy in association with DM and PM.

The types of malignancy associated with the inflammatory myopathies have been varied, including adenocarcinomas of the breast, ovaries, and stomach. Most cases of DM and malignancy seem to occur within 1 year of each other, with myositis diagnosed first in most cases.[123] When a malignancy is identified, removal of the malignancy may result in improvement of the myopathic process, which further supports the paraneoplastic nature of myositis in some cases.[142]

The risk of malignancy may be higher in certain cohorts, including individuals older than 50 years at diagnosis,[143] individuals with evidence of distal extremity weakness,[144] and individuals with prominent pharyngeal and diaphragmatic involvement.[145] Patients who have myositis-associated

**TABLE 123-3**

| Factors That Predict Malignancy in Myositis | Factors Associated with Reduced Risk of Malignancy |
|---|---|
| Age >45 yr | Interstitial lung disease |
| Male gender | Arthritis |
| Dysphagia | Raynaud's phenomenon |
| Cutaneous necrosis | Anti-Jo-1 |
| Cutaneous vasculitis | Anti-ENA |
| Rapid onset of myositis (<4 wk) | Other myositis-specific antibody |
| Shawl sign | |
| Elevated ESR/CRP | |
| Anti–p155-140 (TIF-1γ) and anti-NXP2 (anti-MJ) antibodies | |
| Refractory disease | |

Data from references 147 through 151.

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; TIF-1, transcriptional intermediary factor 1.

autoantibodies may be at less risk for the development of malignancy.[122,144,145] More recent work has suggested that the presence of leukocytoclastic vasculitis,[146] cutaneous ulceration,[145] and an absence of pulmonary involvement[143] further increases the possibility that an underlying malignancy is present. Similar findings were reproduced in a meta-analysis by Lu et al.,[147] who looked at factors predicting malignancy for patients with PM/DM and found that age greater than 45 years, male sex, dysphagia, cutaneous necrosis, cutaneous vasculitis, rapid onset of myositis (<4 weeks), an elevated creatine kinase level, a higher ESR (>35), higher C-reactive protein levels (above the upper limit of normal), and anti–P-155 antibody are all associated with an increased risk of malignancy. Several factors were found to be related to reduced risk, including the presence of interstitial lung disease, arthritis/arthralgia, Raynaud's phenomenon, or anti–Jo-1 antibody and the presence of anti-ENA antibodies (Table 123-3).

In 2006, Targoff et al. described a novel autoantibody against a 155 kDa protein in a large series of patients with myositis.[147a] This antibody was then identified as human transcriptional intermediary factor 1-γ (TIF-1γ), a member of the TIF1 gene family. A recent study has proposed that TIF-1γ is involved in the transforming growth factor-β (TGF-β) signaling pathway, which is inactivated in some malignancies. TIF-1γ acts on TGF-β and is essential in chromatin-mediated transcriptional regulation, functioning as a positive (agonist) or negative (antagonist) regulator of this pathway, which seems to be related to carcinogenesis.[148] The association between cancer and anti-p155 has been confirmed by other investigators, reinforcing this link.[149,150] Antibodies to nuclear matrix protein 2 (NXP-2; anti-MJ) have been found to be specifically associated with cancer in males.[151]

For patients in whom an inflammatory myopathy has been diagnosed, a workup for the presence of malignancy should be performed. The extent of this workup has been debated, however, because extensive undirected searches often result in a very low yield. It is probably rare for an undirected workup to yield evidence of malignancy in patients with PM and DM[152]; any workup should be tailored to the individual patient's age, symptoms, and signs. Studies have suggested that imaging of the chest, abdomen, and pelvis may increase the potential for the discovery of an underlying malignancy.[153,154] Other investigators have suggested the use of serum tumor markers (CA125 and CA19-9) to augment detection of patients with DM or PM who are at highest risk for associated malignancy.[155] More recently, a prospective study of whole-body PET/CT was found to be comparable with broad conventional screening (including chest, abdominal, and pelvic CT scans, among other tests).[156] Malignancies associated with inflammatory myopathies have been known to develop many years after the diagnosis of muscle disease, and thus continued vigilance and repeated screening for malignancy are warranted.

Clinical suggestions include performing a careful history, physical examination, general laboratory screening, stool heme occult ×3, prostate examination/prostate-specific antigen test in men, and Papanicolaou (Pap) smear, mammogram, gynecological examination, and possibly transvaginal sonography and the CA-125 test in women.

## RISK OF MALIGNANCY IN SYSTEMIC AUTOIMMUNE DISEASES

### Lymphoproliferative Disorders

Since the 1960s, reports of the association between rheumatic diseases and the development of malignancies, particularly lymphoproliferative disorders, have been increasing. Table 123-4 shows pre-existing connective tissue diseases that have been associated with malignancy. Much of what is known about associations between rheumatic disease and malignancy is drawn from retrospective and prospective cohort studies, registry-linkage studies, small series, and case reports. This association is thought to be mediated, at least in part, by chronic immune stimulation and hyperactivity that may lead to malignant transformation.[157] In addition, certain confounding factors need to be considered when assessing the risk of the development of malignancy, including the potential oncogenic properties of many of the immunosuppressive and cytotoxic medications prescribed to treat autoimmune diseases. Lymphoproliferative disorders have developed in patients with rheumatic diseases and in recipients of solid organ transplantations treated with immunosuppressive agents. EBV has been implicated in the development of lymphoid neoplasia in immunosuppressed patients. In the following sections, several rheumatic diseases and the therapies used to treat them are discussed.

### Sjögren's Syndrome

Sjögren's syndrome, an autoimmune exocrinopathy, is characterized by a benign lymphocytic infiltrate of salivary and lacrimal glands that leads to the development of sicca syndrome (keratoconjunctivitis and xerostomia).[158] The development of lymphoproliferative disorders in the setting of Sjögren's syndrome is perhaps the prototypic example of chronic autoimmune disease and an increased risk of malignancy. In 1964, investigators first reported the development of four cases of lymphoproliferative disorders in a cohort of

**TABLE 123-4** Pre-existing Systemic Autoimmune Diseases Associated with Malignancy

| Systemic Autoimmune Disease | Malignancy | Associated Factors | Clinical Alert |
|---|---|---|---|
| Sjögren's syndrome | Lymphoproliferative disorders | Glandular features—lymphadenopathy, parotid or salivary enlargement<br>Extraglandular features—purpura, vasculitis, splenomegaly, lymphopenia, low C4 cryoglobulins | Clues to progression from pseudolymphoma to lymphoma include worsening of clinical features, disappearance of rheumatoid factor, and decline of IgM |
| Rheumatoid arthritis | Lymphoproliferative disorders | Presence of paraproteinemia, greater disease severity, longer disease duration, immunosuppression, Felty's syndrome | Rapidly progressive, refractory flare in long-standing rheumatoid disease may suggest an underlying malignancy |
| SLE | Lymphoproliferative disorders | — | Non-Hodgkin's lymphoma should be considered in patients with SLE who have adenopathy or masses; lymphoma of the spleen is another cause of splenic enlargement in SLE |
| Discoid lupus erythematosus | Squamous cell epithelioma | Found in oldest plaques, ≥20 yr after onset of discoid lesion, primarily in men 30-60 yr old | Poorly healing skin lesion within discoid plaques should be evaluated |
| Systemic sclerosis (scleroderma) | Alveolar cell carcinoma<br>Nonmelanoma skin cancer<br>Adenocarcinoma of the esophagus | Pulmonary fibrosis, interstitial lung disease<br>Areas of scleroderma and fibrosis in the skin<br>Barrett's metaplasia | Annual chest radiograph after fibrosis is detected<br>Change in skin features or poorly healing lesions should be evaluated<br>Esophagoscopy and biopsy, if indicated, of distal esophageal constricting lesions |
| Paget's disease of bone | Osteogenic sarcoma | Development of severe pain; increasing incidence with age | Swelling and bone destruction in pre-existing Paget's disease may be sarcoma; diagnosis may require biopsy |
| Dermatomyositis | Ovarian, lung, and gastric cancer in Western populations; nasopharyngeal carcinoma in Asian populations | Older in age, presence of cutaneous vasculitis; less likely in setting of myositis-specific antibodies or interstitial lung disease | Malignancy evaluation needs to be tailored to individual patient's age, symptoms, and signs |

SLE, Systemic lupus erythematosus.

58 patients with Sjögren's syndrome.[159] In 1978, 7 of 136 patients with sicca syndrome were identified as having developed non-Hodgkin's lymphoma. Compared with the expected incidence of cancer among women of the same age range, there was a 44-fold increased risk of developing non-Hodgkin's lymphoma.[160] These findings have been reproduced numerous times in other cohorts. Lymphoproliferative disorders are complications in approximately 4% to 10% of cases of primary Sjögren's syndrome.[161-169] The RR for development of lymphoproliferative disorders in patients with primary Sjögren's syndrome ranges from 6 to 44,[160,169-175] and meta-analyses of cohort studies have found pooled SIRs of 13.8[176] to 18.8.[172] Most lymphoproliferative disorders were non-Hodgkin's lymphoma, specifically diffuse large B cell lymphoma, mucosa-associated lymphoid tissue lymphoma, and other marginal-zone lymphomas.[157,166,167] Waldenström's macroglobulinemia, chronic lymphocytic leukemia, and multiple myeloma were more rarely reported.[160,164,165,171]

Generally, the development of lymphoma is a late manifestation of Sjögren's syndrome; it often is seen after the disease has been present for 6.5 years.[162,163,177] Several clinical and laboratory features seem to be associated with or predictive of the development of lymphoproliferative disorders, including palpable purpura,[159,164,165,175] cutaneous ulcerations,[161] cryoglobulinemia,[165,166] low serum complement levels,[164-166,178] monoclonal gammopathies,[179,180] cytopenias,[159,166,175] splenomegaly,[159,166] and adenopathy.[161] Newer studies have suggested that elevated levels of serum Fms-like tyrosine kinase-3 ligand (Flt-3-L)[181] and evidence of germinal center–like formations in minor salivary gland biopsies[182] are strongly associated with later progression to lymphoma. Progression to high-grade lymphoma portends a poor prognosis.[136,138,139,156,163-165,175] In contrast, with the exception of thyroid cancer (SIR, 2.6; 95% confidence interval [CI], 1.1 to 4.0),[176] the incidence of other malignancies or all-cause mortality was not increased in patients with Sjögren's syndrome compared with the general population.[171,175,177,183] It is believed that chronic B cell stimulation may lead to the malignant transformation of clonal lines characteristic of Sjögren's syndrome.[158] The presence of a viral trigger accounting for malignant transformation is one possible theory. EBV, among other viruses, has been implicated, but studies have failed to find EBV or other viral particles in lymphoma specimens associated with Sjögren's syndrome.[184]

It also has been reported that chromosomal translocations are present with increased frequency in patients with Sjögren's syndrome in whom lymphoma has developed. One group of investigators identified the presence of translocations of the proto-oncogene Bcl-2[185] in five of seven patients

who had Sjögren's syndrome and lymphoma through the use of polymerase chain reaction. Such translocations were found in peripheral blood or bone marrow in 5% of unselected patients with Sjögren's syndrome who did not have evidence of lymphoma in another study.[186] Conversely, no evidence of Bcl-2 translocations was present in 50 salivary gland biopsy specimens of patients with Sjögren's syndrome who did not have evidence of lymphoma.[187] Analysis of biopsy specimens taken before the development of lymphoma from the seven patients previously mentioned showed no evidence of Bcl-2 translocation. Translocation seemed to correlate with the development of lymphoma in at least a subset of patients with Sjögren's syndrome, and the use of polymerase chain reaction technology may allow for early detection of malignant transformation.[186-188]

## Rheumatoid Arthritis

Since the 1970s it has been well established that RA is associated with a twofold to threefold increased risk for the development of lymphoproliferative disorders, the magnitude of which has remained constant despite dramatic changes in therapy. Many factors, including chronic inflammation and immune dysregulation, in addition to potential oncogenic properties of immunosuppressive therapies for the treatment of RA, must be considered when evaluating the risk of the development of hematologic malignancies. It is often difficult to separate the effects of medication use from the underlying severity of inflammation that makes medication use necessary or indicated, a concept termed *confounding by indication*.[189]

In 1978, an SIR of 2.7 for lymphoma was reported in a group of 46,101 Finnish patients with RA compared with the general population.[190] A similarly increased risk of 2.4 for lymphoma was seen later in a group of 20,699 Danish patients,[191] and an SIR of 1.9 to 2 was reported in a large cohort of 76,527 Swedish patients.[192,193] In the United States, an increased risk of 1.9 was found in a cohort of 18,527 patients,[194] and an SIR of 2.2 was found in a separate cohort of 8458 patients aged 65 years and older.[195] An SIR of 2 to 2.4 for lymphoma was observed in an inception cohort of 2015 patients with inflammatory arthritis in England compared with the general population,[196] and an SIR of 2.04 to 2.39 was seen for non-Hodgkin's lymphoma in a cohort of 26,623 patients with RA in Scotland.[197] In a meta-analysis of nine cohort studies of patients with RA, a pooled SIR of 3.9 was found for lymphoma using a random effects model.[173] Canadian investigators found an increased risk of leukemia (SIR, 2.47) among patients with RA but were unable to confirm elevated rates of lymphomas compared with the general population.[198] Data from case-control studies of patients with non-Hodgkin's lymphoma have shown similar results: Odds ratios of 1.3 to 1.5 were found for underlying RA.[172,174] These associations have been confirmed in other populations, including patients from Japan,[199] Taiwan,[200] California,[201] and Spain.[202] In a more recent study of lymphoma risk in biologic-naïve patients with RA in the United Kingdom who were followed up from 2002-2009, an SIR of 3.12 was found for non-Hodgkin's lymphoma and an SIR of 12.82 was found for Hodgkin's lymphoma[203]; these rates are not strikingly different from those seen in the 1970s. In general, lymphomas in patients with RA seem to be predominately diffuse large B cell type and favor non–germinal center subtypes.[204]

Most studies have suggested that the risk for the development of lymphoma is related to the degree of inflammation. The Swedish group identified high inflammatory activity (defined by ESR, swollen and tender joint counts, and the physician's global assessment of disease activity) as a significant risk factor, with an odds ratio of 25.8 compared with low disease activity.[205] No association between any specific drug and the development of lymphoma was identified; however, the cohort examined was treated between 1965 and 1983, and few of these patients were treated with immunosuppressive drugs. In a 2006 follow-up case-control study of 378 lymphomas in a Swedish group of patients with RA, a 71-fold increased risk of lymphoma in patients with high cumulative disease activity compared with low disease activity was seen.[203] Immunosuppressive therapy did not seem to modify the risk for lymphoma in this study. Patients did not have increased rates of lymphoma development prior to disease onset.[206] In a Veterans Affairs study of 906 men, patients with Felty's syndrome (a variant of RA associated with neutropenia and splenomegaly) were found to have a twofold increase in total cancer incidence but a 12-fold increase in the risk of non-Hodgkin's lymphoma.[207]

### Disease-Modifying Anti-rheumatic Drug Therapy

Several studies have looked at the contribution of disease-modifying anti-rheumatic drug (DMARD) therapy to the elevated risk of malignancies in patients with RA. A prospective, observational study was performed in a group of Canadian patients with RA who were enrolled in a DMARD registry.[208] Although study investigators found an increased rate of lymphoproliferative disorders in this cohort compared with the general Canadian population (SIR, 8.05), no significant differences in DMARD exposure were found between patients in whom malignancy did and did not develop. A second group of Canadian investigators similarly identified an increased risk for the development of lymphoma and myeloma in patients with RA overall compared with control groups.[209] In this study, the risk of lymphoma and myeloma seemed to be fourfold greater in the RA group when DMARD use was not controlled for and 3.4-fold greater when individual DMARD use was controlled for. Despite the low level of DMARD exposure in this population, no strong effect of DMARD use was seen.

Similar effects of DMARD use were seen in a study of Swedish patients with RA and lymphoma: Treatment with any DMARD (odds ratio, 0.9) or specific use of methotrexate (odds ratio, 0.8) did not seem to be associated with increased risk of lymphoma compared with DMARD-naïve patients who had RA; however, no patients had been treated with TNF inhibition.[192] In contrast, a European cohort of patients with RA who were enrolled in a DMARD registry was evaluated longitudinally for the development of malignancies.[210] These investigators found an increased risk of lymphoproliferative disorders in patients with the highest cumulative exposure to DMARDs compared with patients who had less than 1 year of exposure (SIR, 4.82).

Although inconclusive, data from these studies when taken together suggest a possible increased risk for the

development of lymphoproliferative disorders in patients with RA who are treated with DMARDs. However, more recent studies have suggested that this increased risk may be due to the duration and severity of the underlying disorder rather than to specific medication use. The introduction and widespread use of TNF inhibitors for the treatment of RA brought theoretical concerns about an increased risk of malignancy as a result of reducing innate tumor surveillance. After approximately two decades of use, use of TNF inhibitors as a class has not been shown to increase risk of lymphoma above the rates in the general RA population.[211] Associations of specific immunosuppressive therapy for the treatment of autoimmune diseases and malignancy is discussed further in Chapters 61 and 62.

### Risk of Solid Tumors

Despite persuasive evidence of increased risks of lymphoproliferative disorders associated with underlying RA, rates of overall all-site malignancies do not seem to be higher compared with the general population.[190-192,197,198,212,213] The overall "null" result of all malignancies is due to the combination of an increased risk of lymphoproliferative disorders offset by an apparent decreased risk of colorectal malignancies.[190-192,197,198,214] The decreased risk of colorectal cancer has been attributed to long-term use of NSAIDs among patients with RA. Aside from lymphoproliferative disorders, only a few solid tumors have been associated with RA, including lung cancer and skin cancer.

An increased risk of lung cancer in patients with RA has been seen in multiple studies.[190-192,197-203,212-214] In a study evaluating three separate RA cohorts (an inpatient registry of 53,067 prevalent cases of RA, an inception cohort of 3703 incident RA cases, and a registry of 4160 patients with RA who were treated with TNF inhibitors), a consistently increased risk of lung cancer was found in all cohorts (SIR, 1.48 to 2.4) compared with the general population.[84,214] This association may be related to tobacco use, which seems to be a common risk factor for the development of RA, in addition to its well-known association with lung cancer,[215] although the particular association of lung cancer among patients with RA who smoke is unknown. Similarly, a study of lung cancer in a cohort of 8768 U.S. veterans (92% male) with RA found an increased risk of lung cancer (odds ratio, 1.43; 95% CI, 1.23 to 1.65) after adjustment for covariates including age, gender, and tobacco exposure.[216]

A slightly increased risk for the development of nonmelanoma skin cancer (most commonly basal cell carcinoma and squamous cell carcinoma) has been noted in several studies,[190,191,214,217,218] although the significance of these tumors, which carry a low probability of metastasis, is unclear. Nonmelanoma skin cancers are rarely captured in national cancer registries, and thus the incidence among the general population or subpopulations, including individuals with RA, is difficult to quantify or compare. Furthermore, important risk factors for nonmelanoma skin cancer, including ultraviolet light exposure, are almost impossible to quantitate in observational studies. Of greater concern, however, is newer data suggesting an increased rate of melanoma among patients with RA.[195,200,218-220] A recent meta-analysis has shown that the risks of both melanoma and nonmelanoma skin cancer appear to be further increased by the use of TNF inhibitors.[211] Because of a suggestion of increased risk of skin cancer, whether attributed to underlying disease or immunosuppressive therapies, it is reasonable to suggest periodic skin examinations in patients with RA, particularly those who have other risk factors including smoking, increased ultraviolet light exposure, and use of TNF inhibitors. Certainly, all suspicious lesions should be evaluated by a dermatologist, and a biopsy should be strongly considered.

## Systemic Lupus Erythematosus

The risks of developing malignancy in association with SLE have become more clear in recent years, as large multicenter, multinational SLE cohorts have been increasingly studied for associations with different comorbidities.[221] The SIR of individual studies has ranged from 1.1 to 2.6.[222] A meta-analysis of six of the clinical cohort studies found a slightly increased risk of overall malignancies in cohorts of patients with SLE, with an SIR of 1.58.[223] This analysis showed an increased risk of lymphomas in these cohorts, with an SIR of 3.57 for non-Hodgkin's lymphoma and 2.35 for Hodgkin's disease. Investigators who performed a separate meta-analysis of the incidence of lymphoma in patients with SLE found an SIR of 7.4.[173] Individual hospital discharge database studies have shown a consistently higher risk of non-Hodgkin's lymphoma (SIR, 3.72 to 6.7), but in these studies only hospitalized patients with SLE were examined.[222]

A series of studies analyzing nearly 9500 patients with lupus (approximately 77,000 patient-years of observation) in a multinational cohort study has helped to define better potential associations with malignancy.[224,225] The authors found a slightly increased risk of malignancies overall (SIR, 1.15), with higher risks for the development of hematologic malignancies (SIR, 2.75), particularly non-Hodgkin's lymphoma (SIR, 3.64).[224] Forty-two cases of non-Hodgkin's lymphomas were identified, most of which were of aggressive histologic subtypes.[226] The incidence of lymphoma in this study appeared to be early in the course of SLE, rather than after many years of chronic disease activity or use of multiple immunosuppressive medications.[225,227] The elevated risk of non-Hodgkin's lymphoma seemed to be independent of race or ethnicity in this cohort, although white patients seemed to have higher rates of malignancy in general compared with patients of other ethnicities.[228] Cancer risks in this multinational cohort have recently been updated in 2013,[229] with 644 malignancies occurring in 16,409 patients with SLE. Risk estimates were similar to earlier studies, but estimates were more precise. The SIR for all hematologic malignancies was 3.20, and it was increased to 4.39 for non-Hodgkin's lymphoma. In a case-cohort study within the multisite international SLE cohort, age, disease-related damage, and smoking were found to be associated with an increased risk of malignancy; use of immunosuppressant medications (particularly lagged 5 years) may contribute to an increased risk of hematologic malignancies.[230]

Although the exact cause of the association is unknown, several theories have arisen to explain the possible connection between SLE and malignancy, especially B cell

lymphoma. Some authors have postulated that certain immunologic defects may predispose patients to SLE and B cell lymphoma, including apoptosis dysfunction, chronic antigenic stimulation, and overexpression of the Bcl-2 oncogene.[221,231] Viruses, EBV in particular, also have been postulated to be part of the development of SLE and lymphoma.[221,231] Studies have not conclusively validated any of these theories to date, however. More recently, elevated levels of APRIL (A Proliferating-Inducing Ligand) has been found in sera and tumor specimens in patients with SLE who have non-Hodgkin's lymphoma.[232] This cytokine has long been associated with SLE itself and may suggest a common pathway between SLE and lymphoma.[221]

The relative prevalence of cervical cancer in patients with SLE is difficult to estimate because national cancer registries often do not record malignancies in situ. Cervical cancer remains an important issue for women with SLE, and an increased risk may come about for different reasons, including (1) reduced clearance of human papilloma virus, the causal agent in the majority of cervical cancer cases; (2) increased risks of cervical cancer associated with immunosuppressive medications; and (3) reduced rates of routine Pap smears and other screening procedures in a population of patients with chronic illnesses. In a large multinational study performed more recently, the SIR for invasive cervical cancer was found to be elevated at 1.26, albeit with confidence intervals that cross the null.[224,229] Other studies have confirmed an increased risk of abnormal Pap smears and cervical dysplasia in women with SLE.[233-239] In a recent meta-analysis of published studies, a pooled SIR of high-grade squamous intraepithelial lesions of the cervix was found to be 8.66 compared with control subjects.[237] Different studies have implicated increased prevalence of human papillomavirus infection and other sexually transmitted diseases,[235,238-240] and immunosuppression[234,238,240,241] may partly explain this association. As with mammography, women with SLE seem less likely to undergo routine Pap testing than do women in the general population.[242,243] Interestingly, data have suggested a reduced risk of hormone-sensitive tumors among patients with SLE, including breast, endometrial, and possibly ovarian and prostate tumors.[221,229] Reasons for these associations remain unclear.

In several studies, a link has been identified between SLE and the development of lung cancer.[227] Indeed, the largest multinational cohort of subjects with SLE found an increased incidence of lung cancer compared with the general population (SIR, 1.30; 95% CI, 1.04 to 1.60).[229] Further analyses of the cases of lung cancer in this cohort reveal a variety of tumor types, including adenocarcinoma, bronchoalveolar carcinoma, squamous cell carcinoma, small cell carcinoma, large cell carcinoma, and carcinoid tumor.[244] The majority of cases (71%) occurred in smokers, 25% of cases were in men, and few (20%) had previous exposure to immunosuppressive agents.[244]

Overall, the presence of SLE carries a risk for the development of cancer, particularly non-Hodgkin's lymphoma, lung cancer, and cervical cancer. The underlying causes of these associations are unknown, but they do not seem to be exclusively related to the use of immunosuppressive or cytotoxic agents.[221,230,245-248] Data also suggest that patients with lupus may be less likely to receive recommended cancer screening.

## Systemic Sclerosis

Although data are conflicting, most evidence suggests that people with systemic sclerosis (SSc) seem to have an increased risk of developing malignancy.[249,250] Estimates of the prevalence of cancer among patients with scleroderma range from 3.6% to 10.7%.[250,251] However, 13% of deaths among patients with SSc are caused by cancer.[252] The malignancies that have been implicated are often in organs affected by inflammation and fibrosis, including the lung, breast, esophagus, and skin. The SIR of malignancy in the scleroderma population is 1.5 to 5.1 compared with that of the general population.[253-258] There is an apparent increase in the observed number of cases of lung cancers that occur in the setting of pulmonary fibrosis but not in association with tobacco use.[257,259] In a different study evaluating 20 lung cancers among 632 patients with scleroderma in Australia, it was found that cigarette smoking, but not underlying pulmonary fibrosis, was associated with an increased risk of lung cancer.[260] Study findings have been mixed regarding an increased risk or temporal relationship between scleroderma and breast cancer.[250,253,261]

A meta-analysis of more than 7000 patients with scleroderma indicated that compared with the general population, the summary RR to develop all invasive cancers in patients with scleroderma was 1.75 (95% CI, 1.41 to 2.18). A strong association with lung cancer (RR, 4.35; 95% CI, 2.08 to 9.09) and a significant increased risk for hematologic neoplasms (RR, 2.24; 95% CI, 1.53 to 3.29) was seen. The relationship with breast cancer, which was suggested in some previous epidemiologic studies, was not confirmed (RR, 1.05; 95% CI, 0.86 to 1.29). Similar results were reported by Zhang et al.[262] in another meta-analysis of 7183 patients with scleroderma, with an SIR of 3.14.[262]

Data are mixed regarding associations between SSc-specific autoantibodies and the development of cancer. Selected studies support potential associations,[256,263] whereas others do not.[257,264] Shah et al.[265] reported a close temporal relationship with cancer (within 1 to 2 years of scleroderma diagnosis) in patients with scleroderma who had positive antibodies for RNA polymerase I/III. Interestingly, expression of RNA polymerase I and RNA polymerase III were detected in the tumors of affected individuals.[265] Similar findings were reported in a large single-center United Kingdom retrospective cohort study of 2177 patients with SSc[266]; 7.1% had a history of cancer, 26% had anticentromere antibodies (ACAs), 18.2% had anti-Scl-70 antibodies, and 26.6% were positive for anti-RNA polymerase III (anti-RNAP) antibody. The major malignancy cancer subtypes were breast (42.2%), hematologic (12.3%), gastrointestinal (11.0%), and gynecologic (11.0%). The frequency of cancers among patients with anti-RNAP (14.2%) was significantly increased compared with patients with anti-Scl-70 antibodies (6.3%) and ACAs (6.8%; $P < 0.0001$ and $P < 0.001$, respectively). Among the patients who were diagnosed with cancer within 36 months of the clinical onset of SSc, there were more patients with anti-RNAP (55.3%) than with other autoantibody specificities (ACA = 23.5%, $P < 0.008$, and anti-Scl-70 antibodies = 13.6%, $P < 0.002$, respectively). Breast cancers were temporally associated with the onset of SSc among patients with anti-RNAP.

The precise pathogenic mechanisms that cause and maintain an autoimmune response in patients with cancer have not been fully elucidated. Autoimmunity in cancer may occur as a consequence of an abnormal self-antigen expression and/or mutated antigens, as well as of tumor-derived biologic substances produced by cancer cells. In addition, the consequences of chronic inflammation and fibrotic processes may damage tissue, cells, and DNA, leading to altered immune responses and the development of malignant transformation, triggering the development of lung cancer or cutaneous malignancies. Researchers from Johns Hopkins recently reported genetic alterations of the POLR3A locus in six of eight patients with antibodies to RNA polymerase III but not in eight patients with scleroderma who had other autoantibody specificities. Analyses of peripheral blood lymphocytes and serum suggested that POLR3A mutations triggered cellular immunity and cross-reactive humoral immune responses.[267]

Although the SIR for all malignancies is 1.5 to 2.4, the incidence ratio for lung cancer and non-Hodgkin's lymphoma can be as high as 7.8 and 9.6, respectively. Cases of non-Hodgkin's lymphoma seem to be more likely to occur within the first year of the diagnosis of SSc.[255] Elevations in incidence also were found for other specific cancers, including nonmelanoma skin cancers (4.2), primary liver cancers (3.3), and hematopoietic cancers (2.3)—all having a higher incidence than that in the general population. The greatest risk seems to correspond to areas commonly affected by fibrosis, particularly the lung and skin. Esophageal involvement, which is common in limited and diffuse SSc, is the likely cause for an increased incidence of Barrett's esophagus (12.7%)[268] and the development of esophageal cancer (SIR, 9.6).[269] In contrast to the aforementioned data, one study found no increase in overall or specific malignancies in patients with SSc (SIR, 0.91 overall).[264] Localized scleroderma, including morphea or linear scleroderma, does not seem to convey an increased risk of malignancy.[270]

Sclerodermatous skin changes have been reported with breast, ovarian, pulmonary, and gastrointestinal cancer. Several reports have described the development of post-irradiation morphea in patients treated for breast cancer.[271]

## PRIMARY TUMORS AND METASTATIC DISEASE

### Primary Musculoskeletal Tumors

This section does not provide in-depth knowledge of the primary tumors of the musculoskeletal system. Rather, it provides a reference to the most common primary malignant musculoskeletal tumors and symptoms that may arise in association with them. The primary tumors of bone, including benign and malignant tumors, are discussed in more detail in Chapter 124.

A primary malignant bone cancer is any neoplasm that develops from the tissues or cells found within bone and has the ability to metastasize. Neoplasms may develop or arise from any of the types of cells present within the bone—osteoblasts, chondrocytes, adipose and fibrous tissue, vascular cells, hematopoietic cells, and neural tissue.[272] A neoplasm developing from any of these tissues is called a sarcoma, which signifies that it is derived from mesenchymal tissue. The bone sarcomas are named for the predominant differentiated tissue type, such as osteosarcomas, chondrosarcomas, liposarcomas, and angiosarcomas.[272]

The most common manifestation of these tumors is the development of pain in the area of the lesion, which may be accompanied by a sympathetic effusion or stiffness in the surrounding joint. This discomfort does not seem to be activity related and is often worse at night. However, these tumors can manifest as painless masses or as pathologic fractures. Systemic features such as fatigue, malaise, weight loss, fevers, and night sweats are rare with all of these tumors except for Ewing's sarcoma.[272] Primary malignant bone tumors are uncommon, particularly compared with other types of cancer. They have their highest incidence in childhood and adolescence and constitute 3.2% of childhood malignancies that occur before age 15 years. The incidence has been reported in this age group as 3 per 100,000 individuals.[237] These tumors commonly arise out of areas of rapid growth, with the most common site of primary bone sarcomas being the metaphysis near the growth plate.[273]

Table 123-5 lists the most common types of primary malignant bone tumors. Osteosarcoma is the most common of the tumors and generally occurs in individuals in the second decade of life or in elderly individuals.[274] Osteosarcoma also can occur as a result of radiation therapy delivered as treatment for other malignancies. Paget's disease of bone can rarely (in <1% of cases) proceed to malignant transformation.[275] Severe pain in the setting of Paget's disease may signal transformation to osteogenic sarcoma. Tumors most frequently affect the femur, humerus, skull, and pelvis and can result in pathologic fractures. Survival is usually less than 1 year. Differentiation of malignancy from Paget's disease may require a biopsy.[276,277]

Chondrosarcoma has been reported as the second most common of the malignant bone tumors. This tumor may occur as a primary tumor or as a malignant transformation in the setting of benign lesions, such as an enchondroma or osteochondroma.[278] Fibrosarcoma is significantly less common than the previously mentioned tumors and accounts for less than 4% of primary malignant bone tumors.[279]

As a group, round cell tumors include primary lymphomas of bone, Ewing's sarcoma, and metastatic neuroblastoma. Ewing's sarcoma is a common primary bone tumor of childhood. Giant cell tumors as a group account for 4.5% of bone tumors. They usually arise from the metaphysis or epiphysis of long bones, generally around the knee. Most are benign, but a few are malignant lesions, usually arising out of a previously irradiated benign giant cell tumor.[272]

In addition to the primary malignancies of bone, a plethora of malignant tumors can arise from mesenchymal connective tissue; these tumors are also known as sarcomas.[279,280] They can result in joint symptoms but more often

**TABLE 123-5** Primary Bone Tumors

result in soft tissue symptoms. They are very rare. Rhabdomyosarcoma is a malignant tumor arising from muscle tissue. It is the fourth most common solid tumor in children and is responsible for more than half of all soft tissue sarcomas in children. Rhabdomyosarcoma rarely occurs in adults. It can appear at any site, and the symptoms are most often referable to the site involved. Most commonly, rhabdomyosarcoma affects the orbits, genitourinary tract, limbs, head and neck, and parameningeal areas. It commonly metastasizes to the lymph nodes, lungs, and bone.[273,281]

### Metastatic Disease

When bone lesions are identified, primary tumors need to be considered, although most malignant lesions in bone are metastatic. Metastasis rarely affects muscles, joints, or adjacent connective tissue; more commonly, it affects bone. The most common sites of metastasis are the spine and pelvis. It is uncommon to find metastatic lesions distal to the elbow, and, although rare, metastasis to the foot is more common than to the hand.[282] When distal or acral metastasis is identified, it is often associated with lung cancer.[283] Primary tumors generally associated with metastases to bone include tumors in the prostate, thyroid, lung, breast, and kidney.[284] Although most skeletal metastases do not produce pain, one of the most common causes of cancer-related pain is the infiltration of bone. The pain can be intense and stabbing or dull. It is often constant rather than intermittent, is worse at night, and often is worse with weight bearing and movement.[285] Rheumatic or arthritic symptoms often can occur before lesions are easily identified on radiographs. Arthritis associated with metastatic carcinoma is most commonly monarticular and usually affects the knee. Metastases to the hip, ankle, wrist, hand, and foot have been reported but occur less frequently. Breast and lung carcinomas are present in most patients.[286] Metastases to the extremities can simulate gout, osteomyelitis, tenosynovitis, or acro-osteolysis. The development of joint involvement can be related to direct synovial implantation or involvement of the juxta-articular or subchondral bone.[287] Table 123-6 presents the clinical features suggestive of underlying metastases.

Radiographic features of bone tumors can be significant when interpreting the duration of disease and the type of malignancy. Lesions may be lytic or blastic, and patterns of destruction often reflect the aggressiveness of tumors. Well-circumscribed lesions may be more indicative of slower growth, whereas a "moth-eaten" pattern with evidence of cortical destruction typically signifies a more rapid rate of growth. What has been described as a permeative pattern suggests an extremely rapid rate of destruction and is often associated with an extraosseous soft tissue mass.[272] CT, MRI, and radionucleotide imaging also can provide significant information for diagnosis, staging, prognosis, and therapy.

## POST-CHEMOTHERAPY RHEUMATIC DISEASE

Several rheumatic or musculoskeletal manifestations can develop in patients after administration of chemotherapy for the treatment of malignancy. Post-chemotherapy rheumatism has been best described in patients treated for breast cancer, but it also has been described in other malignancies, including ovarian cancer and non-Hodgkin's lymphoma.[288-290] The phenomenon has been described as a non-inflammatory, self-limited, migratory arthropathy. Typically symptoms develop several weeks to several months after the completion of chemotherapy and often include myalgia, stiffness, arthralgia, and arthritis involving the small joints of the hands, ankles, and knees.[289] Post-chemotherapy rheumatism can be mistaken for RA based on its symptoms; however, most patients have little or no evidence of synovial thickening and have no radiographic or serologic evidence to suggest RA. The pathogenesis of this process is unknown; however, it is self-limited, usually lasting less than 1 year, and is best treated in a conservative fashion. Evaluation should be performed to exclude recurrent carcinoma or another inflammatory condition. The medications most frequently implicated in this phenomenon are cyclophosphamide, 5-fluorouracil, methotrexate, and tamoxifen.[290-292]

Other immunomodulatory agents also have been linked to the development of musculoskeletal findings. Tamoxifen use has been associated with the development of an acute inflammatory arthritis similar to RA[292]; however, a randomized controlled trial of tamoxifen or placebo in 7145 women at high risk for breast cancer (but without a diagnosis of cancer) did not find an increased prevalence of arthralgia or arthritis symptoms in the tamoxifen arm.[293] More recently, aromatase inhibitors have been used widely for hormone receptor–positive breast cancer, with increasing reports of associated arthralgia and arthritis. A retrospective, exploratory analysis of the Arimidex Tamoxifen Alone or in Combination (ATAC) trial evaluated the development of joint symptoms in 5433 women with early stage breast cancer who were randomized to receive either anastrozole alone or tamoxifen alone.[294] When analysis was limited to women who entered the study without joint symptoms at randomization, 35.2% experienced joint symptoms while taking anastrozole compared with 30.3% who experienced joint symptoms while taking tamoxifen ($P$ <0.0001). However, the intensity of symptoms was not different between groups. A prospective, nonrandomized study evaluated the prevalence of musculoskeletal symptoms in women who switched from anastrozole to letrozole as a result of articular symptoms.[295] The majority (61%) were able to continue with letrozole, with 28.5% discontinuing the second aromatase inhibitor as a result of severe musculoskeletal symptoms.

Therefore, switching aromatase inhibitors may be a reasonable strategy when an initial agent is intolerable because of arthralgia or arthritis; however, many women continue to be intolerant to more than one agent.

Biologic agents used for the treatment of chronic viruses or a variety of malignancies can similarly lead to an autoimmune phenomenon. Use of IL-2 can result in spondyloarthritis or inflammatory arthritis. Interferon-α administration can result in seropositive nodular RA and myalgia and arthralgia.[296,297] The use of interferon also can result in autoantibody formation and features suggestive of SLE and autoimmune thyroid disease.[297-299]

## Lymphoproliferative and Myeloproliferative Diseases

### Leukemia

Leukemia can result in the development of musculoskeletal symptoms. Bone pain is the most common musculoskeletal manifestation and has been reported to occur in 50% of adults with leukemia.[300] Long bone pain is more common in children, whereas axial pain is more common in adults. Generally, the bone pain is more common in the lower than in the upper extremities.[301] Overt synovitis can develop in association with acute and chronic leukemia and can result in the development of monarticular or polyarticular arthritis.[302] The pathogenesis seems to be leukemic infiltration of the synovium and subperiosteal tissue. Bleeding or hemorrhage in the joint also may be associated with the process. Most cases of arthritis associated with leukemia are seen in children (14% to 50% compared with 4% to 16.5% in adults).[303-305]

In a series of adult patients with acute leukemia who were studied over a 10-year period, 5.8% (8 of 139) of the patients presented with rheumatic manifestations. On average, symptoms of arthritis preceded the diagnosis of leukemia by 3.25 months.[306] The most common patterns of presentation were an asymmetric large joint involvement in association with low back pain, followed by symmetric polyarthritis mimicking early RA. Rheumatic manifestations included morning stiffness, low back pain, nonarticular bone pain, pain out of proportion to objective findings, low-grade fever, and elevation of the ESR. The response to NSAIDs, glucocorticoids, and conventional anti-rheumatic therapy was reportedly poor, but tumor-directed chemotherapy resulted in substantial improvement of the rheumatic manifestations. Patients with these manifestations also were more likely to exhibit early osteopenia or lytic bone lesions. Ultimately, prognosis and mortality rates were no different between patients presenting with or without rheumatic manifestations.[306]

In contrast, in a large retrospective study of children with leukemia, it was found that 21.4% (36 of 168) with acute lymphoblastic leukemia and 10.5% (6 of 57) with acute nonlymphoblastic leukemia experienced symptoms associated with bones and joints. In 13 of these patients with acute lymphoblastic leukemia, radiographs showed evidence of bony lesions.[307]

Many of these children had been incorrectly treated for juvenile RA or osteomyelitis before the diagnosis of leukemia. The group with bone lesions seemed to do very well, and their condition might fall into a subgroup of childhood leukemia that has a better prognosis.[302,307] A more recent study found that the presence of subtle blood cell count changes and nighttime pain may help distinguish leukemia from juvenile RA.[305]

### Multiple Myeloma

Multiple myeloma is a neoplastic proliferation of plasma cells—a nonosseous malignant tumor arising in the marrow. In contrast with the other primary tumors of bone, which have their highest incidence in children and adolescents, myeloma is a tumor of adults, occurring most commonly in the fifth and sixth decades of life. The most common musculoskeletal feature of this disease is the development of bone pain. Other hallmark features are diffuse pain and stiffness. Patients characteristically experience osteopenia, and osteolytic lesions are seen on radiographs. The lytic lesions, which can occur in any area of the skeleton, are produced by focal accumulations of plasma cells. Osteosclerotic lesions also have been reported.[308] True arthritis is rare, but cases of arthritis resulting from articular and periarticular invasion with malignant cells have been reported in individuals with multiple myeloma and Waldenström's macroglobulinemia.[309] A secondary feature of the disease, which can often lead to additional musculoskeletal complaints, is the development of hyperuricemia and secondary gout. Sjögren's syndrome and other autoimmune phenomena also have been described in association with multiple myeloma.[310]

### Lymphoma

Musculoskeletal symptoms have been reported in 25% of cases of non-Hodgkin's lymphoma.[311] The most common musculoskeletal problem associated with lymphoma is the development of bone pain associated with metastases or lymphoma in the bone. By report, more than 50% of patients have evidence of bone lesions at autopsy; however, few patients actually present with arthritis or bone pain.[302,312] Nonetheless, non-Hodgkin's lymphoma has been reported to manifest as a seronegative arthritis with or without other features, such as lymphadenopathy and hepatomegaly, typically seen with this disease. Monarticular and polyarticular involvement can occur. Cases have been reported of polyarthritis simulating RA in the setting of non-Hodgkin's lymphoma.[313] Although it is unusual to see direct involvement of the synovium, this finding also has been reported. There have been cases with radiographic evidence of bone destruction associated with non-Hodgkin's lymphomatous arthropathy.[314] Suspicion of lymphoma should be heightened in patients in whom severe constitutional symptoms seem out of proportion to the degree of arthritis, especially in patients who are negative for rheumatoid factor.

### Angioimmunoblastic Lymphadenopathy

Angioimmunoblastic lymphadenopathy is a rare lymphoproliferative disorder marked by the clinical features of lymphadenopathy, hepatosplenomegaly, rash, and hypergammaglobulinemia. Patients can experience a nonerosive, symmetric, seronegative polyarthritis concurrent with other

**TABLE 123-7** Musculoskeletal Manifestations of Hematologic Malignancy

| Malignancy | Pathogenesis |
|---|---|
| Leukemia | Infiltration of synovium |
| Lymphoma | Metastases or invasion of bone, rarely joint |
| Angioblastic lymphadenopathy | Vasculitis, cryoglobulinemia |
| Multiple myeloma | Metastasis or invasion of bone, hyperuricemia |

features or as an initial symptom of the disease.[315-317] Similar features have been reported with intravascular lymphoma, with a report of a patient presenting with a symmetric polyarthritis accompanied by fever.[318] Table 123-7 lists musculoskeletal symptoms found with hematologic malignancy.

### Graft-Versus-Host Disease

Graft-versus-host disease is a complication of bone marrow transplantation and a major cause of morbidity and mortality in the transplant population. Numerous musculoskeletal symptoms arise in the setting of acute graft-versus-host disease (lasting 0 to 3 months) and in chronic graft-versus-host disease (lasting >3 months after transplantation). The most frequent manifestation is the involvement of the skin, which in many cases can progress to resemble the changes of SSc. Skin changes consistent with eosinophilic fasciitis also have been reported.[301] Graft-versus-host disease can lead to symptoms of keratoconjunctivitis sicca and xerostomia resembling Sjögren's syndrome. Other features including arthralgias, arthritis, myositis, Raynaud's phenomenon, and serositis also have been reported.[301]

## CONCLUSION

A plethora of factors contribute to the development of musculoskeletal syndromes in the setting of autoimmune disease and malignancy. A great many autoimmune disorders exist, and for most of them, the underlying cause and pathogenesis have not been elucidated. Because of this incredible diversity, understanding the relationship between associated symptoms is often difficult. To make any generalizations regarding the association between an autoimmune disorder and the subsequent development of malignancy, large numbers of patients must be studied longitudinally for exceptionally long periods. Other confounders complicate the picture. For example, many of the agents used in the treatment of connective tissue and autoimmune disorders modulate the immune system. These agents may have direct carcinogenic potential, whereas others may affect the immune system in a way that may decrease tumor surveillance and subsequently lead to the development of a neoplasm. Intricately entwined are the unique differences of individual immune systems not only in healthy individuals, but also in individuals whose immune systems are already altered based on an underlying autoimmune disorder. Although uncommon, it is plausible that virtually any of the autoimmune-based diseases and the agents used to treat them might be associated with malignancy in certain circumstances. Most important, when musculoskeletal symptoms arise, malignancy or paraneoplastic syndromes should be considered in the differential diagnosis, especially when patients present with atypical features of autoimmune disease or are refractory to conventional treatment. In addition, the potential for any agent to induce a neoplastic process must be weighed against its proposed benefits before initiating it as therapy.

CHAPTER 124

# Tumors and Tumor-like Lesions of Joints and Related Structures

Darcy A. Kerr • Andrew E. Rosenberg

## KEY POINTS

**Most mass lesions that involve joints and synovial-lined structures are benign. Synovial cysts, which are the most common, are not true cysts because they lack an epithelial lining. Synovial cysts may involve joints (e.g., a Baker's cyst) or tendon sheaths, and when the synovial lining is inconspicuous, they are designated ganglion cysts. Treatment depends on the symptoms; observation is a reasonable course of action in many cases.**

**Synovial chondromatosis is an uncommon benign condition characterized by nodules of hyaline cartilage, often ossified, within the subsynovial connective tissue, most frequently involving the knee. These nodules can be confused with osteochondral loose bodies, and treatment consists of removal of the nodules.**

**Tenosynovial giant cell tumor of joints and tendon sheaths is the most common neoplasm of synovial-lined structures. The tumor is most often monoarticular, with the knee involved in 80% of cases. The neoplastic cells overexpress macrophage colony-stimulating factor as a result of a chromosomal translocation. Although the tumor is benign, it can be locally destructive. Treatment consists of removal of the tumor, and new forms of targeted medical therapy are now available.**

**The most common primary malignant tumor of joints is synovial sarcoma, which usually affects children and young adults. The disease has an aggressive course, with a long-term survival of approximately 50%.**

**Lymphoproliferative diseases, especially acute leukemia, may involve joints. Joint involvement is most common in children, for whom the reported incidence ranges from 12% to 65%. Arthritis caused by leukemic infiltration of the synovium can occur at any time in the course of the disease and can be the presenting symptom.**

Synovial-lined joints and periarticular structures are often affected by mass-forming lesions. Arthrosis, arthritis, trauma, and structural derangements produce the most common lesions, which are non-neoplastic and include ganglions, synovial cysts, and loose bodies. In contrast, it is uncommon for neoplasms, whether benign or malignant, to develop in joints and periarticular structures.

Joint neoplasms can be divided into tumors that are primary or arise de novo within the synovium and tumors that are secondary and access the joint by invading from neighboring bones and soft tissues or by spreading from distant sites via the vascular system. Primary joint neoplasms are more common and tend to recapitulate the phenotype of tissues that normally compose the joint and synovial sheath—synovium, fat, blood vessels, fibrous tissue, and cartilage. Regardless of the histologic type, benign variants greatly outnumber their malignant counterparts, and as a group these tumors develop more frequently in the synovium, in comparison with other periarticular structures.

Tumors and tumor-like lesions of the joints and periarticular structures are biologically and morphologically diverse. They often pose significant challenges in diagnosis and treatment, and their clinicopathologic features are the focus of this chapter.

## NON-NEOPLASTIC LESIONS

### Synovial and Ganglion Cysts

Cysts are defined as closed compartments or sacs that are lined by epithelium and are frequently filled with fluid. Neither the synovial cyst nor the ganglion cyst is considered a true cyst because each lacks an epithelial lining.

Synovial cysts are common and develop from the synovial lining of a joint, tendon, or bursa. They are non-neoplastic lesions caused by herniation of the synovium through the joint capsule or tendon sheath into neighboring tissues or by expansion of a pre-existing bursa. In adults, synovial cysts frequently develop in association with a variety of joint disorders, including trauma, osteoarthrosis, crystal arthropathies, infection, and rheumatoid arthritis or one of its variants. Most synovial cysts have an anatomic attachment to a joint, and most originate in the posterior medial aspect of the knees of adults, where they are known as popliteal or Baker's cysts. Anatomically, this region of the knee is prone to the development of synovial cysts because the joint capsule can be structurally insufficient and because people in this age group often have co-existing joint disease.[1,2] Synovial cysts of the posterior knee joint are purported to affect 2.4% of children, who, in contrast to adults, are usually asymptomatic and have an otherwise normal knee joint.[3] Other joints affected by synovial cysts in decreasing order of frequency are the shoulder, hip, and spine. In the spine they originate from the facet joints and are most commonly located in the lower lumbar region.

Synovial cysts can enlarge over time as they become further distended with increasing amounts of synovial fluid.[1,3-5] Consequently, they may manifest as a periarticular mass, produce progressive joint pain and swelling, limit

joint mobility, and compress adjacent neurovascular structures. An example of compression occurs in the spine, where synovial cysts that arise from facet joints may impinge or extend along spinal nerves, causing radicular pain.[6-8] Other complications of synovial cysts, which sometimes can produce dramatic clinical findings, are acute rupture and secondary infection.

A variety of radiographic techniques have been used to create images of synovial cysts. Modalities that provide the greatest diagnostic information include arthrography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI).[1,3-5] All of these techniques reveal synovial cysts to be simple or septated thin-walled structures that are filled with fluid, with a density similar to that of water (Figure 124-1).

Grossly, synovial cysts usually range in size from 1 to 10 cm. Their inner surface is smooth, glistening, and translucent; however, it can be distorted by an attached blood clot, inflammatory debris, or granulation tissue resulting from a prior hemorrhage or infection. The inner surface of the cyst wall is lined by flattened or plump cuboidal synoviocytes arranged in one or several cell layers and surrounded by an outer sheath of fibrous tissue (Figure 124-2). Sometimes the synovial lining cells may be hyperplastic and form papillary fronds of varying size; other findings that may develop are scattered subsynovial collections of hemosiderin-laden macrophages from previous hemorrhage and aggregates of mononuclear cells and reactive fibrosis resulting from chronic irritation. Facet joint cysts often contain abundant amorphous debris surrounded by macrophages and are associated with severe degenerative changes of the ligamentum flavum and its elastic fibers and the annulus fibrosus.

The treatment of synovial cysts varies, depending on their location and associated symptoms. They can be managed successfully with conservative therapy; however, in certain clinical situations, surgical excision is required.[1,3-8]

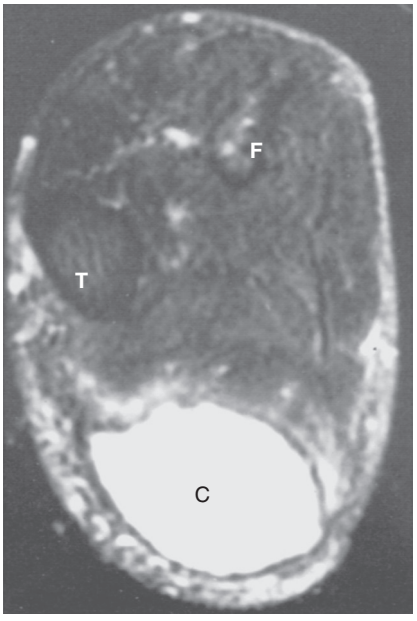

**Figure 124-1** MRI shows a large, oval-shaped synovial cyst with high T2-weighted signal intensity that extends from the knee joint into the posterior calf. C, Synovial cyst; F, fibula; T, tibia.

Ganglion cysts have been recognized for centuries; Hippocrates described them as being composed of "mucoid flesh."[9] They are more common than synovial cysts and arise from tendon sheaths, ligaments, menisci, joint capsules, and bursae.[9] Occasionally they develop de novo in the subchondral areas of bone (intraosseous ganglion), and rarely, they arise within nerve or skeletal muscle and lack communication with a joint. Intraneural ganglia develop from dissection of joint fluid along an articular branch of a nerve.[10] Ganglion cysts are distinguished from synovial cysts by virtue of the fact that they lack a surface lining of synoviocytes.[11] A variety of hypotheses have been proposed to explain their pathogenesis, but none has been proven.[9] The most accepted theory is that ganglia develop from mucoid cystic degeneration of periarticular structures and are lined by fibroblast and myofibroblast-like cells.[11] They are commonly associated with repetitive motion activities, inflammatory arthritides, and trauma.

Most ganglia arise along the dorsal and volar aspects of the wrists and fingers and the dorsum of the feet.[9,12] They are usually asymptomatic and typically manifest as a slowly growing, mobile, firm mass that moves with the structure from which it has arisen (Figure 124-3). Ganglia may be painful if traumatized and can compress adjacent

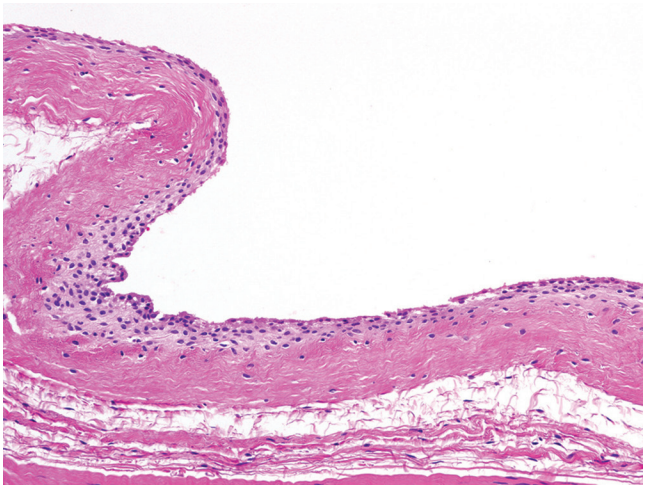

**Figure 124-2** The wall of a synovial cyst that is composed of an inner lining of synoviocytes overlaying a layer of dense, fibrous tissue.

**Figure 124-3** A round, firm ganglion cyst bulging from the dorsal aspect of the hand.

neurovascular structures, producing a variety of symptoms. The radiographic characteristics of ganglia are similar to those of synovial cysts, and they appear on images as small, fluid-filled cystic structures.[1,12] However, with use of ultrasound, ganglion cysts are generally more difficult to compress than synovial cysts because of the thicker, more viscous content and denser capsule of the ganglion cyst; this difference may allow the sonographer to distinguish these two entities through sonocompression characteristics.[2]

Macroscopically, most ganglia are round, but they may form elongate cylindrical structures if they track along a tendon sheath. Ganglia are uniloculated or multiloculated, have thin walls, and are filled with translucent mucoid fluid rich in hyaluronic acid and other mucopolysaccharides (Figure 124-4). The cyst lacks a distinct inner cell lining, and the bulk of the wall consists of dense fibrous tissue, which is usually surrounded by areolar tissue (Figure 124-5).

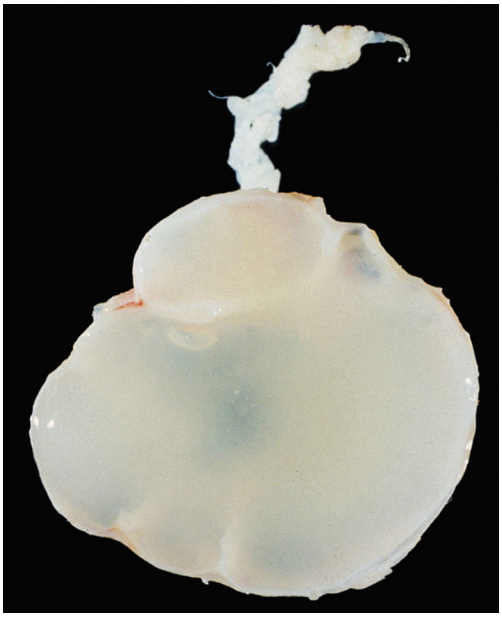

**Figure 124-4** An intact ganglion cyst with a thread-like pedicle that attaches to a periarticular structure.

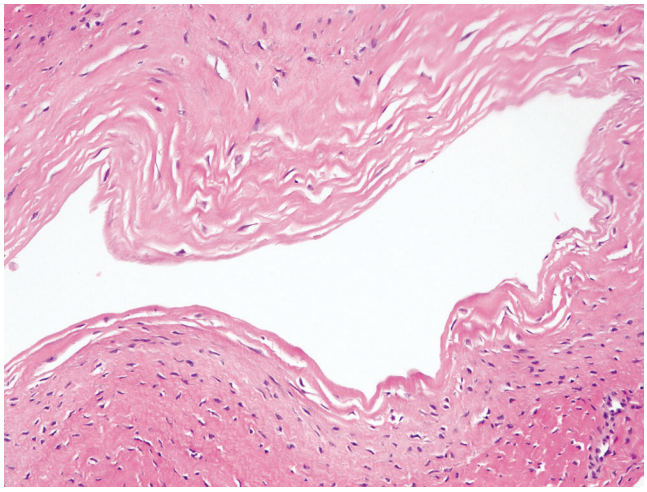

**Figure 124-5** A ganglion cyst wall composed of scattered flattened fibroblasts on the luminal surface and a well-formed layer of fibrous tissue.

In many instances, the cyst wall is distorted by variable quantities of reactive myxoid tissue and muciphages, which result from small ruptures and extravasation of fluid.

When ganglion cysts form, they may remain stable for years or may spontaneously resolve, and ganglia that disappear may subsequently redevelop. Treatment is frequently conservative because of their innocuous nature. Ganglia occasionally require aspiration or surgical excision, however, especially if they are symptomatic.

## Loose Bodies

*Loose bodies* and *joint mice* are generic terms for free-floating structures within a joint cavity. They are the most common tumor-like lesions of joints and may be exogenous, such as fragments of a bullet, or endogenous, such as pieces of articular cartilage, osteophytes, menisci, ligaments, or bone.[13-15] When not otherwise specified, the term *loose bodies* refers to detached pieces of articular cartilage or subchondral bone (osteoarticular loose bodies) or both that lie free within the joint or that have become secondarily embedded in the synovium. Loose bodies can cause pain, crepitance, and locking, and they can limit the range of joint motion.

Osteoarticular loose bodies are a secondary complication of a variety of conditions, including trauma, osteochondritis dissecans, and arthritides of various causes. When dislodged, the sloughed articular cartilage remains viable because it receives its nourishment from the synovial fluid, but the subchondral bone dies because it derives its nutrition solely from blood vessels. Over time, as the loose body tumbles within the joint, its edges become rounded and smooth; however, it eventually becomes embedded within the synovium. Subsequently, the synovium may digest and resorb it, or adjacent subsynovial connective tissue cells may undergo a proliferative and metaplastic response. These cells produce layers of newly formed fibrocartilage and hyaline cartilage, which may undergo endochondral ossification and are deposited on the surface of the loose body (Figure 124-6). These layers of newly formed tissue surround the centrally located dislodged native structure, similar to the cambium layers of a tree, and provide a mechanism for the entire structure to increase gradually in size and become significantly larger than the initial osteochondral defect from which it originated (Figures 124-7 and 124-8). As the

**Figure 124-6** A large, nodular loose body formed from a semilunar-shaped piece of articular cartilage that is surrounded by newly formed cartilage.

**Figure 124-7** A loose body with visible layers of newly formed tissue.

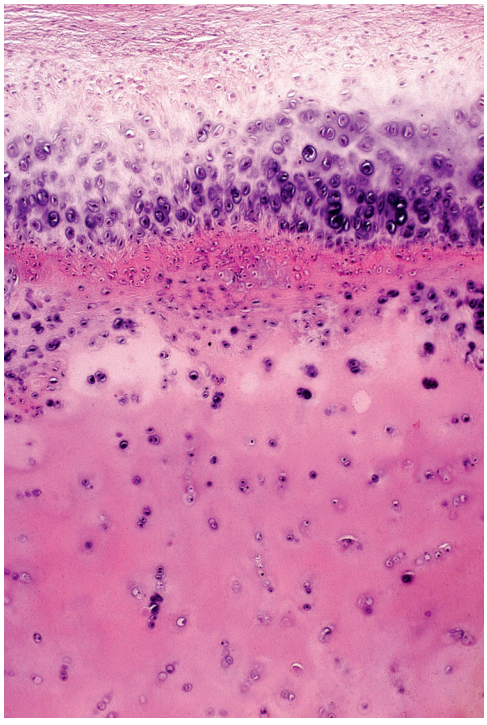

**Figure 124-8** A loose body composed of sloughed articular hyaline cartilage *(bottom)* covered by consecutive layers of newly formed metaplastic hyaline cartilage and bone.

loose body enlarges, the innermost portion of original articular cartilage cannot be supported adequately by diffusion of synovial fluid, and it dies and calcifies. This combination of events causes the loose body to appear on radiographs as dense, speckled, and ring-like calcifications (Figure 124-9). Radiographically and histologically, the differential diagnosis includes synovial chondromatosis. Treatment is simple excision, which can be performed arthroscopically.[14,15]

### Intra-articular Ossicles

Small bony nodules normally occur in the knees of some rodents[16] and other mammals, and they may rarely occur in humans.[17-19] In rodents, small bony nodules are consistently found in the anterior portions of the joint and frequently in the posterior portions as well. In humans, nodules develop within the substance of the meniscus of the knee joint adjacent to its attachments to the tibia.

**Figure 124-9** A knee with an osteoarticular loose body in the suprapatellar region *(arrow)*.

The exact origin of such structures is unknown, although they probably are true sesamoid bones, as seen in rodents. Alternatively, they may represent ossification resulting from local injury. This latter possibility is supported by the fact that previous knee trauma has been noted in numerous reported cases. The main symptom of meniscal ossicles is pain after exertion, such as walking or prolonged standing, with relief when the knee is at rest. Radiographs may reveal an intra-articular calcification that can be confused with a loose body. MRI shows the ossicle to be a corticated marrow-containing structure that has increased signal intensity on T1-weighted images and decreased signal intensity on T2-weighted images.[17,19] The ossicle is located within the lateral or the medial meniscus and appears as a small (~1 cm in diameter), palpable, bony nodule (Figure 124-10).[18] If the ossicle is symptomatic, it should be excised; however, if it is an incidental finding, it can be managed conservatively.[17,19]

## NEOPLASMS

### Fatty Lesions of the Synovium

Although the subsynovial connective tissue of diarthrodial joints is rich in fat, a true lipoma of the synovium is rare. When lipomas develop, they most frequently affect the knee joint and the synovial tendon sheaths of the hands, ankles, and feet, where they are more common in the extensor than in the flexor synovial sheaths.[20,21] Synovial lipomas can be sessile or pedunculated, and when pedunculated, they may produce pain if they twist on their stalks and become secondarily ischemic. Synovial lipoma, similar to

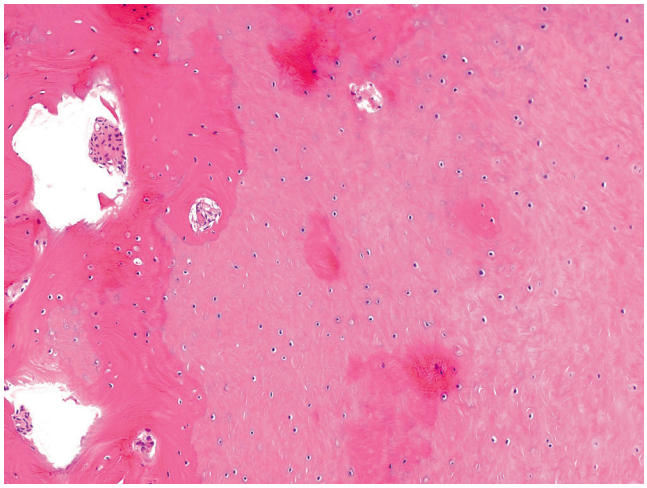

**Figure 124-10** An intra-articular ossicle embedded in the fibrocartilage of the meniscus.

**Figure 124-11** Lipoma arborescens manifesting as a suprapatellar mass.

its subcutaneous counterpart, is composed of lobules of mature white adipocytes that are delineated by a thin fibrous capsule.

A more common but still unusual fatty lesion of the joint is lipoma arborescens, also known as *villous lipomatous proliferation* and *lipomatosis of the synovium*.[22,23] This disorder is characterized by a diffuse increase in the quantity of subsynovial fat, which bulges into the overlying synovial lining, producing a villous architecture. It is uncertain whether the proliferating fat is neoplastic (lipomatosis) or is a manifestation of a hyperplastic or reactive process. Most cases occur in the context of degenerative or inflammatory arthritis, supporting the idea that the fatty proliferation may represent a secondary reactive process in most instances.[24] Affected patients are usually adults, but the lesion sometimes develops in adolescents and rarely in children.[25] In younger patients, lipoma arborescens may occur in the absence of an identifiable etiologic agent and affect joints other than the knee, raising the possibility of a distinct primary form of the disease.[24] Lipoma arborescens causes chronic effusions, pain, and swelling and restricts joint motion.[23] The duration of symptoms is often long, and symptoms have been reported to be present for as long as 30 years; however, acute onset has been documented.

Lipoma arborescens most commonly arises in the knee (Figure 124-11), especially the suprapatellar portion, although it also has been observed in the hip, ankle, and wrist joints. One study found that nearly a third of cases demonstrate an atypical presentation, with multifocality or disease outside of the knee.[24] Lipoma arborescens is typically localized to one joint, but several cases of bilateral knee involvement have been described.[23] Laboratory studies are unremarkable, and the joint fluid is clear and yellow.[23] Plain films show joint fullness, and findings of osteoarthritis are often present. Arthrography reveals multiple lobulated filling defects, which on CT represent a villonodular mass of low signal intensity that on MRI has the density of fat (Figure 124-12).[26] At surgery, the affected synovium is seen to have a prominent villous or villonodular architecture and is tan-yellow (Figure 124-13). Histologically, the lesion is composed of sheets of mature adipocytes admixed with

**Figure 124-12** MRI of lipoma arborescens shows a villonodular mass in the knee joint.

nutrient blood vessels, all of which are partially compartmentalized by fibrous septa, and it is covered on its intra-articular surface by several layers of synovial cells (Figure 124-14). Synovectomy may relieve the symptoms and prevent effusions, but associated osteoarthritis may be progressive.[23]

The clinicoradiologic differential diagnosis includes diffuse tenosynovial giant cell tumor, synovial chondromatosis, and synovial hemangioma. These lesions can be distinguished easily from lipoma arborescens by their distinct histologic features. Another disorder that should be included in the differential diagnosis is Hoffa's disease, which is a

**Figure 124-13** Lipoma arborescens composed of a villonodular mass of fatty tissue covered by glistening synovium.

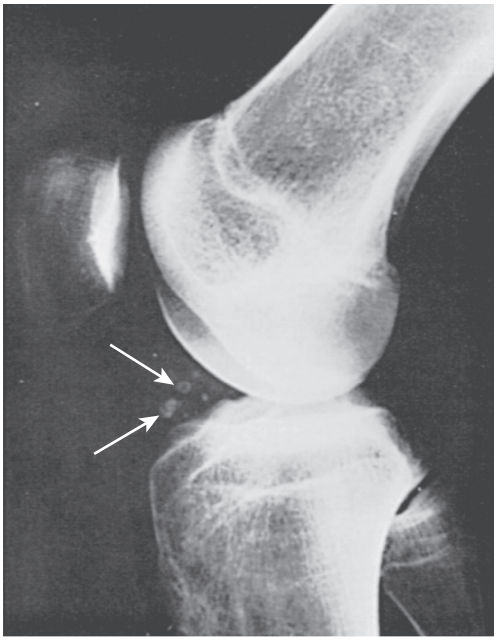

**Figure 124-15** A localized synovial hemangioma with phleboliths prominently seen in the joint *(arrows)*. The patient is 16 years old and has had painful swelling for many years when standing and relief of this pain when the knee is flexed.

condition of irritation, inflammation, and hyperplasia of the synovial lining in regions where fat is normally present, such as adjacent to the patella or patellar ligament.[27]

## Vascular Lesions of the Synovium

Benign vascular tumors of the synovium are rare. Their growth pattern can be localized or diffuse. They tend to predominate in adolescence and young adulthood, but symptoms frequently can be traced back to childhood.[28] The joint most commonly involved is the knee, but hemangiomas also have been described in the elbow, the ankle, the tarsometatarsal and temporomandibular joints, and the tendon sheaths of the wrist and ankle.[29,30] Unusual complications of synovial hemangiomas include a secondary destructive arthritis and Kasabach-Merritt syndrome.

Synovial hemangiomas produce a variety of symptoms, including unilateral, intermittent joint pain and enlargement, which may result in limitation of motion, locking, buckling, and hemarthrosis, especially after minimal trauma.[29] Classically, the affected joint diminishes in size if it is elevated to a sufficient degree to allow the blood to drain out of the lesion. Upon physical examination, the joint is swollen and doughy, and nearby cutaneous hemangiomas may be evident. Joint aspiration frequently yields bloody fluid. Pre-operative diagnosis of localized hemangioma is difficult; the differential diagnosis includes localized tenosynovial giant cell tumor, and in the knee it includes discoid meniscus, meniscal tears, cysts, and ossicles.[23] The diffuse hemangioma is more easily identified, but it can mimic diffuse tenosynovial giant cell tumor and hemophilic arthropathy.

Radiographic evaluation may show nothing more than a vague soft tissue shadow indicative of a swollen synovium and a distended joint capsule or regional osteoporosis in patients who have had long-term symptoms and recurrent hemarthrosis. Rarely, calcified phleboliths are apparent; however, they are more often associated with a soft tissue arteriovenous malformation with secondary joint involvement than with an isolated intra-articular hemangioma (Figure 124-15). Arthrography may show an intra-articular filling defect, and arteriography may be negative in small localized capillary hemangiomas, but contrast material may collect in the more diffuse lesions that contain cavernous or large ectatic vascular spaces (Figure 124-16). CT reveals a lobulated soft tissue mass with mild enhancement after injection of contrast material.[30] MRI may show that the

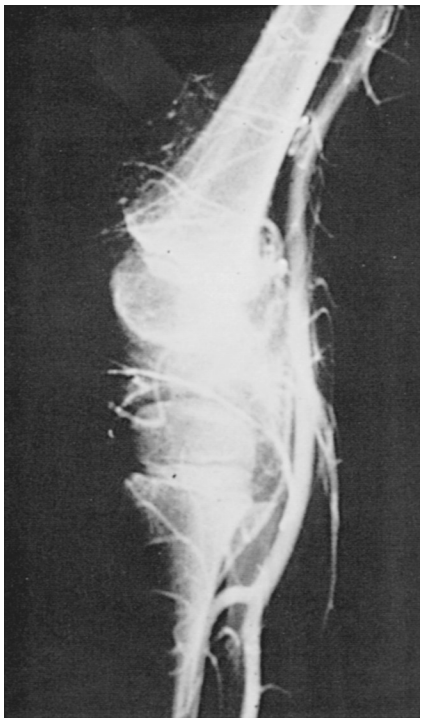

**Figure 124-16** An arteriogram of an arteriovenous malformation in the soft tissues of the thigh and leg with involvement of the knee joint. The extensive vascular blush in the knee indicates aberrant synovial and capsular vasculature.

tumor has a low to isointense signal on T1-weighted images and high signal intensity on T2-weighted images.[31]

Macroscopically, the localized hemangioma tends to be small, but larger lesions (8 cm) have been documented.[31] The hemangioma may be poorly defined or well circumscribed, sessile, or stalked, and it ranges in color from red to dark blue-purple. Microscopically, the hemangioma is usually of the cavernous or venous type, with large dilated blood-filled vessels lined by cytologically benign endothelial cells. In arteriovenous hemangioma, which grows in a diffuse fashion, the entire synovium may be edematous and beefy red or stained brown by hemosiderin, and it consists of prominent tortuous, congested vessels that may penetrate the joint capsule and extend into neighboring soft tissues. Histologically, the vessels recapitulate architecturally abnormal arteries, veins, and capillaries; have abnormal interconnections; and are arranged in a disorganized tangle.

Therapy for a localized hemangioma is marginal surgical excision, which usually is curative. Diffuse lesions frequently are difficult to eradicate because of their extensive nature. Incomplete excision or debulking may be the only surgical option. Radiation therapy is not indicated.

## Fibroma of the Tendon Sheath

Fibromas of the tendon sheath are uncommon benign neoplasms that clinically mimic tenosynovial giant cell tumors but are morphologically distinct. Fibroma of the tendon sheath was first identified as a clinicopathologic entity in 1936, and since that time, more than several hundred cases have been reported.[32,33] A translocation t(2;11) (q31-32;q12) has been identified in this tumor and is likely the driver of the neoplastic process. A translocation t(9;11)(p24;q13-14) also has been documented as an alternative translocation involving 11q in a fibroma of the tendon sheath; therefore, different molecular aberrations are associated with this neoplasm.[34]

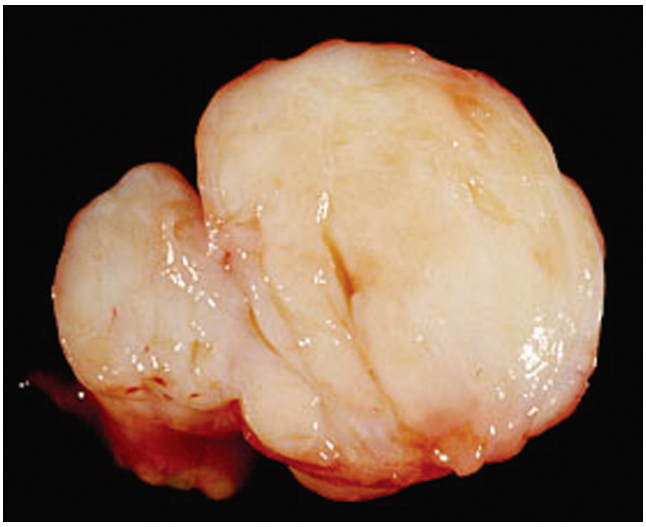

**Figure 124-17** A fibroma of the tendon sheath that formed a well-circumscribed, tan-white mass.

Fibromas of the tendon sheath usually arise from the tendons and sheaths of the flexor surfaces of the distal extremities; approximately 70% of cases involve the fingers or hand. Of the fingers, the thumb is most frequently affected, followed in descending order by the index and middle fingers.[32] Less commonly, large diarthrodial joints such as the knee and rarely the elbow and ankle are sites of origin.[32,33,35] Patients range in age from infants to elderly individuals, but the median age is the early fourth decade of life.[32,33] Most series report a male predominance, with the largest study of 138 cases having a male-to-female ratio of 3:1.[32] Patients present with a slow-growing, painless mass that usually has been noted for several months to a year.[33] In 6% to 10% of cases, a history of antecedent trauma is reported. Tumors developing in large joints can be painful and restrict range of motion, and they may be palpable.[36]

Plain radiographs show soft tissue fullness; rarely is there evidence of bone erosion.[32] CT or MRI shows a solid, well-circumscribed mass of soft tissue density that usually has low signal intensity on T1-weighted images and variable intensity on T2-weighted images. At surgery, the tumors are often attached directly to the tendon or tendon sheath. They are rubbery, oblong, well circumscribed, or encapsulated; average 1.5 to 1.8 cm in their greatest dimension; and have a tan-white cut surface (Figure 124-17).[32,33]

Microscopically, fibromas of the tendon sheath are multilobular, with clefts interposed between adjacent lobules. The lobules are composed of spindle and stellate fibroblasts enmeshed in a collagenous and sometimes myxoid stroma (Figure 124-18). Hypercellular regions reminiscent of nodular fasciitis may be seen. Immunohistochemically, the tumor cells have the staining profile of myofibroblasts, and ultrastructurally, the cells have features of fibroblasts and myofibroblasts.[37]

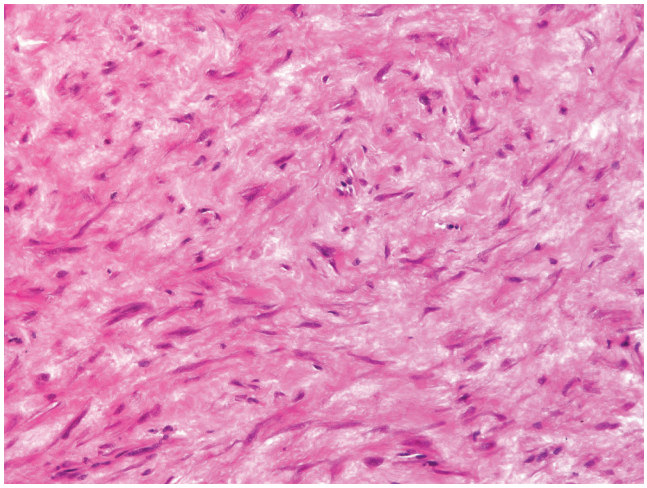

**Figure 124-18** A fibroma of the tendon sheath composed of a hypocellular collagenous mass.

The natural history of a fibroma of the tendon sheath consists of slow growth that eventually ceases. The treatment of choice is surgical excision, but a 24% recurrence rate has been reported.[32]

## Synovial Chondromatosis

Synovial chondromatosis is an uncommon condition characterized by the formation of multiple nodules of hyaline cartilage within the subsynovial connective tissue. If the cartilage nodules undergo endochondral ossification, the term *synovial osteochondromatosis* is appropriate. It is unclear whether the proliferating cartilage is metaplastic or neoplastic; however, more recent cytogenetic abnormalities involving chromosome 6 that are present in the chondrocytes of these lesions support a neoplastic process.[38] Regardless, synovial chondromatosis is benign and does not metastasize.

Synovial chondromatosis most commonly affects middle-aged men, with an average age in the fifth decade of life.[39] In middle-aged women, the disease is more likely to develop in the temporomandibular joint. The genders are equally affected with regard to hand and foot involvement, and patients with hand and foot involvement are usually in their sixth decade.

Patients commonly describe joint pain, swelling, stiffness, crepitance, and limitation of motion with a locking or grating sensation upon movement.[39] Symptoms are usually long-standing, recurrent, and progressive.

Synovial chondromatosis typically arises in large diarthrodial joints. The knee is affected in more than 50% of cases, usually as a monoarticular condition.[39] Other common sites include the hip, elbow, shoulder, and ankle. Infrequently, synovial chondromatosis arises in the small joints of the hands and feet and in the temporomandibular joint.[40] When cartilage nodules develop in the synovial lining of bursae, tendons, and ligaments, this condition is known as *extra-articular synovial chondromatosis*.[36] The extra-articular variant most commonly affects the fingers, followed by the toes, hand, wrist, foot, and ankle, and more than one synovial sheath may be involved.[36]

**Figure 124-19** Synovial chondromatosis of the elbow. Multiple large calcified bodies fill the joint space and are adjacent to bone.

Findings of plain radiographs largely depend on whether the cartilage nodules are calcified or ossified and whether they erode adjacent bony structures. Visible calcifications are absent in 5% to 33% of cases; however, most often, multiple oval intra-articular radiodensities range in size from a few millimeters to several centimeters (Figure 124-19).[41] The pattern of mineralization varies and may appear as irregular flecks that represent calcified cartilage or show a trabecular architecture, which is a manifestation of endochondral ossification. Lesions that are not mineralized can be seen on an arthrogram because they produce multiple filling defects. In approximately 11% of cases, nodules erode the neighboring skeleton, especially along the anterior aspect of the distal femur.

CT may show mass-like nodules in the synovium that have a density similar to skeletal muscle. CT also can detect small calcifications and erosions before they are apparent on plain films. MRI shows that the nodules of cartilage have low signal intensity on T1-weighted sequences and high intensity on T2-weighted sequences, which reflects the high water content of the hyaline cartilage.[41] Areas of calcification or mineralized bone have a low signal intensity on T1-weighted and T2-weighted sequences. CT and MRI scans are helpful in identifying the intra-articular source of the lesion and its anatomic extent. In long-standing disease, the bones adjacent to involved joints may be osteoporotic and may show changes of secondary osteoarthritis.

The cartilage in extra-articular synovial chondromatosis has similar radiographic changes.[41] Nodules of cartilage are frequently mineralized and may appear as a linear arrangement of small calcific densities that are aligned along the sheath and can span many joints (Figure 124-20).

The radiographic differential diagnosis of synovial chondromatosis includes osteochondritis dissecans, osteoarthritis

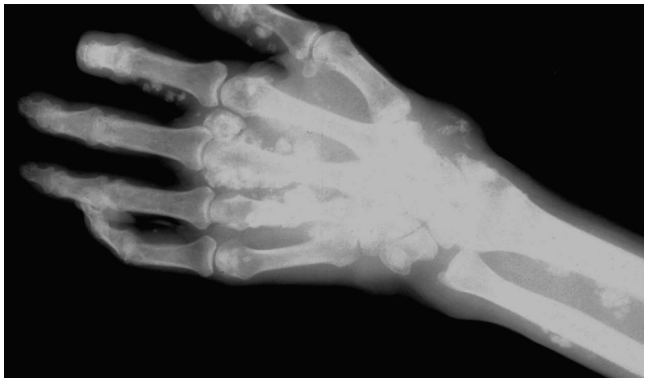

**Figure 124-20** Synovial chondromatosis of the hand and forearm. Multiple calcified nodules of varying size are evident in the soft tissues of the fingers, wrist, and forearm.

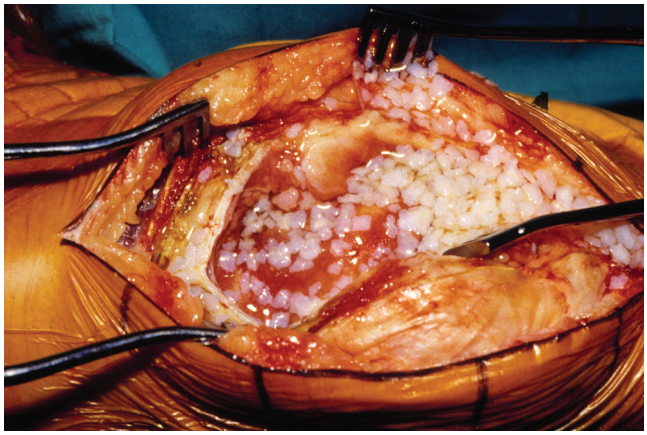

**Figure 124-21** Intraoperative appearance of synovial chondromatosis. Innumerable nodules of cartilage fill the joint.

with loose bodies, tuberculosis, hemopathic arthropathies, pseudogout with extensive synovial calcification, and synovial tumors. In many instances, the clinical presentation and the radiographic picture should lead to the correct diagnosis. However, in a significant proportion of cases, radiographs and the clinical picture are vague, and thus only a biopsy specimen can remove all doubt about the diagnosis.

Characteristic of synovial chondromatosis is a thickened synovium containing numerous opalescent, firm nodules of cartilage that bulge from the surface in a cobblestone pattern (Figure 124-21). These nodules usually measure less than 5 cm and may lose their attachment to the synovium and form loose bodies, sometimes numbering in the hundreds. The calcified cartilage is white, and areas of ossification manifest as gritty tan trabeculae, which may house fatty marrow. The synovium adjacent to the cartilage may show reactive changes, such as edema, hyperemia, hyperplasia, and villous transformation.

The cartilage nodules develop in the connective tissue of the subsynovial compartment (Figure 124-22). Neoplastic chondrocytes produce the hyaline matrix that eventually forms individual nodules, which peripherally abut the surrounding tissues (Figure 124-23). The cartilage varies in its cellularity, and chondrocytes range from small to large; some may be binucleate and hyperchromatic, similar to the

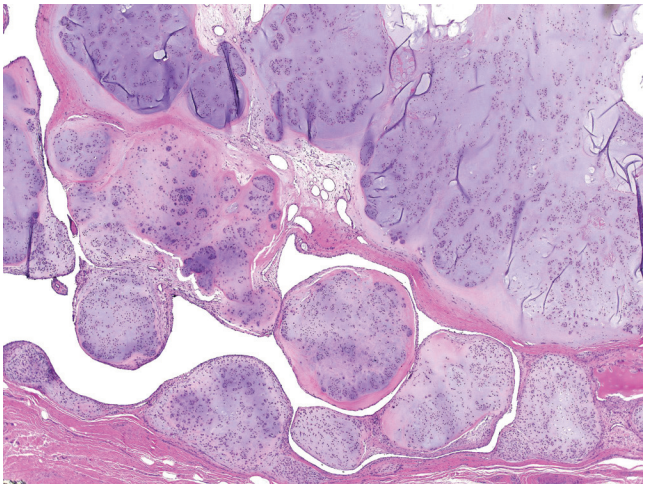

**Figure 124-22** Synovial chondromatosis with nodules of hyaline cartilage in the synovium.

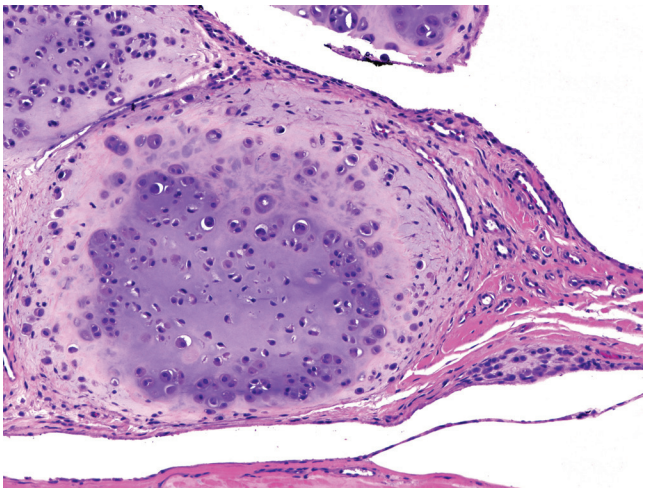

**Figure 124-23** Nodules of hyaline cartilage merging with surrounding connective tissue in synovial chondromatosis.

chondrocytes in intraosseous chondrosarcoma (Figure 124-24). Despite these histologic findings of concern, experience has shown that hypercellular variants with atypical chondrocytes usually behave in a benign fashion. Infrequently, the disease manifests as a single, solitary nodule of cartilage, which may be very large and may undergo partial endochondral ossification (synovial osteochondroma). Intra-articular osteochondroma can severely limit joint motion and may be confused clinically with other types of neoplasms.[42]

Over time, nodules of cartilage attached to the synovium can be invaded by blood vessels, which initiates the process of endochondral ossification, with woven and lamellar bone formation and the development of a medullary cavity with fatty marrow (Figure 124-25). If these nodules lose their synovial attachments and become free-floating, they may continue to increase in size because the cartilage derives its nourishment from synovial fluid, although the osseous portion and the marrow die.

The treatment of choice for synovial chondromatosis consists of excision of the involved synovium and removal of all loose bodies. The prognosis is good, although

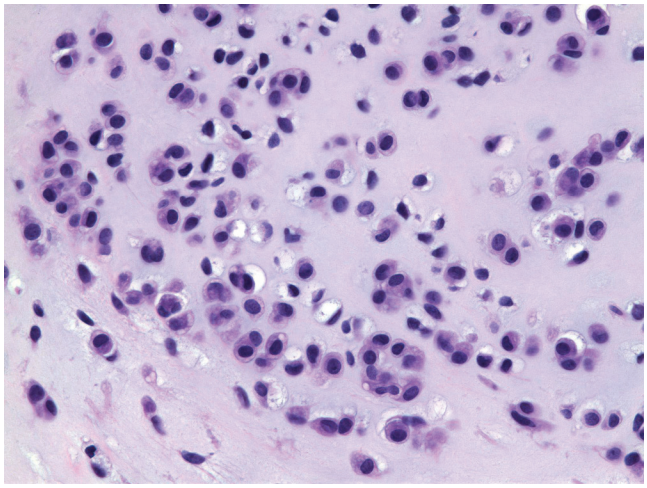

**Figure 124-24** The cartilage in synovial chondromatosis can be cellular, and the chondrocytes may exhibit limited cytologic atypia.

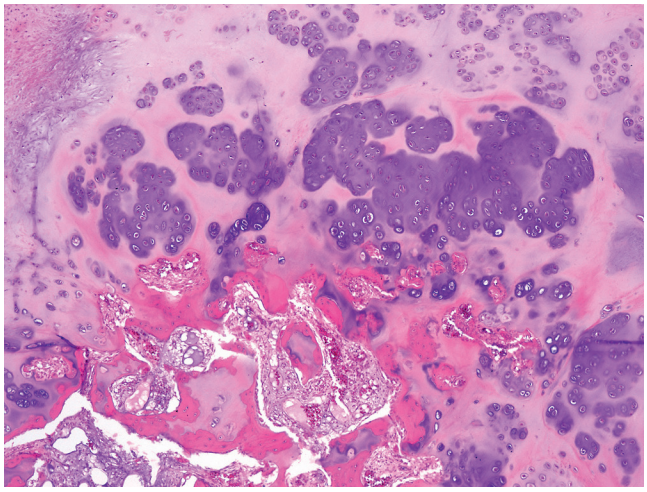

**Figure 124-25** Nodules of cartilage in synovial chondromatosis undergoing endochondral ossification.

recurrences may develop if removal is incomplete. Most recurrences occur in the setting of diffuse involvement of the synovium.

Synovial chondromatosis rarely undergoes malignant transformation into chondrosarcoma, although in one series, this phenomenon occurred in 6.4% of cases.[43] However, a significant percentage of the reported cases of synovial chondrosarcomas have shown evidence of underlying synovial chondromatosis.[44-46] The chondrosarcomatous component exhibits marked hypercellularity, severe cytologic atypia, and prominent mitotic activity; the stroma is often myxoid.

## Chondroma of Tendon Sheath and Periarticular Structures

Solitary soft tissue chondroma is a benign neoplasm that commonly arises in tendon sheaths and infrequently involves joint capsules or other periarticular structures.

Tendon sheath chondromas usually arise in the flexor tendon sheaths of the distal extremities and are about three

**Figure 124-26** An intra-articular solitary chondroma of the knee in the infrapatellar region. The mass is well delineated with amorphous dense calcification, suggesting mineralized cartilage. *(Courtesy Dr. C. Campbell.)*

times more common in the hands than in the feet.[47-49] They affect the sexes equally and are detected in early to mid adulthood, presenting as a painless, slowly growing, firm mass. Radiographically, tendon sheath chondromas appear as an extraosseous, well-delineated soft tissue mass that contains calcifications, which are punctate or ring-like in 33% to 70% of cases.[50,51] Grossly, the tumors are ovoid, firm, blue-white, well-circumscribed masses of hyaline cartilage that are usually 1 to 2 cm in dimension and, in contrast to synovial chondromatosis, are solitary. Histologically, the hyaline cartilage is well formed with occasional small foci of myxoid change. The cartilage can be cellular, and chondrocytes may show limited cytologic atypia, which sometimes causes confusion with chondrosarcoma.[52] The treatment of choice is simple excision, which is infrequently associated with local recurrence.[48,49,52]

The intracapsular and periarticular regions are uncommon sites for soft tissue chondromas. When they occur, they usually originate in the anterior infrapatellar region of the knee (Figure 124-26).[53] In this location, chondromas can achieve a large size (8 cm) and may interfere with knee motion. Their structure and biologic behavior are similar to those of soft tissue chondromas that arise elsewhere. Intracapsular chondromas have been reported in the knees of three members of a family with familial dysplasia epiphysealis hemimelica.[50] Two other cases have been described in which cartilaginous hamartomas of the volar plates of the proximal and distal interphalangeal joints of the hands and feet were associated with peculiar hypertrophic skin lesions of the hand and hemihypertrophy of the limb.

## Tenosynovial Giant Cell Tumor

Tenosynovial giant cell tumors comprise a group of benign tumors that affect the synovial lining of joints, tendon

sheaths, and bursae.[51] These lesions were previously known as *giant cell tumor of the tendon sheath*, *localized nodular synovitis*, and *pigmented villonodular synovitis*. Tenosynovial giant cell tumors may be localized or diffuse and intra-articular or extra-articular. They have the potential to be locally aggressive in that they may invade into bone, grow through joint capsules, extend along tendons, and infiltrate into adjacent soft tissues. Despite their destructive potential, these lesions generally do not have the capacity to metastasize.

The common histologic denominator of these lesions is the neoplastic proliferation of synovial-like cells that may form a localized mass or spread along the synovial surface and invade downward into subsynovial connective tissue. The growing cells expand the subsynovial compartment, producing finger-like extensions, villi, and redundant folds. These projections often fuse into nodules and form convoluted lobulated masses admixed with a tangle of hair-like villi. The process may be a local phenomenon involving only part of the synovial lining, or it may be extensive, with the entire synovial surface affected.

Until recently, the origin of tenosynovial giant cell tumor was unknown. Previously considered a reactive process, possibly in response to repeated hemorrhage, many tenosynovial giant cell tumors result from a translocation between chromosomes 1p13 and 2q35 in which the gene encoding macrophage colony-stimulating factor 1 (M-CSF; also called colony stimulating factor 1 [CSF1]) *(CSF1)* is fused to the collagen VI alpha-3 *(COL6A3)* gene.[51,54,55] Consequently, overexpression of CSF1 occurs in the neoplastic cells, which account for only 2% to 16% of cells in the mass.[54] The remaining cells largely represent nonneoplastic inflammatory cells that are recruited into the tumor because they contain the receptor for MCSF/CSF1 (CSFR1).[54,55] This phenomenon has been termed a *landscape effect* and is also observed in certain types of lymphomas and sarcomas. A subset of tumors demonstrates high M-CSF expression in the absence of the 1p13 translocation, suggesting the presence of alternate mechanisms of M-CSF elevation in a proportion of cases.[56] Indeed, novel M-CSF transcripts and a *CSF1-S100A10* fusion gene resulting from a translocation t(1;1)(q21;p11) have been described, which may help elucidate additional mechanisms of M-CSF overexpression in this disease.[57]

### Tenosynovial Giant Cell Tumor of Joints and Tendon Sheaths: Diffuse Type (Pigmented Villonodular Synovitis)

The diffuse type of tenosynovial giant cell tumor of the joint involves large areas of the synovial lining, although uninvolved areas are invariably present. Its incidence is approximately 1.8 per 1 million. Although it may occur in all age groups, spanning children to elderly people, most of these tumors affect adults who are in the third to fourth decade of life.[58] The sexes tend to be equally affected, although some series have reported a predominance of males or of females.[58-60] Diffuse tenosynovial giant cell tumor of the joint usually manifests as monoarticular arthritis. Bilaterality or involvement of multiple separate sites has been infrequently reported. Some patients with polyarticular disease also have had significant congenital anomalies. Primary complaints include pain and effusions that can be intermittent with repeated bouts of over a long time, ranging from months to years.[58,60] The involved area may be stiff, swollen, and warm, and a palpable mass sometimes can be appreciated. Point tenderness is detected in approximately 50% of patients. Anatomic instability of the involved joint is uncommon.

The knee joint is affected most commonly and is involved in about 80% of cases.[58,60] The next most frequent sites are the hip, ankle, calcaneocuboid joints, elbow, and tendon sheaths of fingers and sometimes toes. Occasionally, the palm, the sole of the foot, and unusual locations such as the temporomandibular joint and posterior elements of the spine are involved. Bursal involvement is rare, but if it happens, it usually occurs in the popliteal and iliopectineal bursae and the bursa anserina. Infrequently, the disease affects large tendon sheaths proximal to the ankle and wrist and produces a periarticular soft tissue mass.[61,62] It is thought that some of these lesions dissect through a joint capsule or a tendon sheath and extend along fascial planes to produce a soft tissue mass.[61]

Invasion of bone on either side of a joint can be seen with intra-articular, bursal, or tendon sheath involvement. This phenomenon most frequently occurs when the tumor involves "tight" joints, such as the hip, elbow, wrist, and feet, or when tendon sheaths are closely apposed to neighboring bones (Figure 124-27).[63,64] Rarely, only one bone may be invaded by an intra-articular lesion, and in this situation, it may be difficult to distinguish this type of lesion from a primary bone tumor (Figure 127-28).[65]

Joint aspiration frequently yields blood-tinged brown fluid that lacks diagnostic abnormalities.[66] Synovial fluid analysis may show a low glucose content, a minimally elevated protein level, and a fair mucin clot. The inflammatory cell count is usually low but may be elevated. Similar findings can be seen in trauma, Charcot's joint, bleeding disorders, sickle cell disease, and Ehlers-Danlos syndrome.

**Figure 124-27** Pigmented villonodular synovitis involving the small joints of the foot with multiple bone erosions. No calcification is present in the lesion.

In at least two-thirds of cases, a soft tissue density due to the tumor or effusion or both can be visualized on a plain film.[67-70] Joint narrowing or calcification is uncommon. Arthrography may show numerous nodular filling defects that extend into an expanded joint space. Arteriograms are unusually striking as a result of the prominent vascularity of the tumor. An inverse correlation tends to exist between the degree of vascularity and the amount of fibrosis or scarring of the lesion.

CT and MRI are useful in delineating the extent of disease and can detect intralesional lipid and hemosiderin deposits, which are important diagnostic features.[67-69] The tumor has low signal intensity (equal to that of skeletal muscle) on T1-weighted images and is heterogeneous on T2-weighted images. Extension into the bone manifests radiographically as multiple, well-marginated, subchondral cyst–like lucencies or juxtacortical oval pressure erosions (see Figures 124-27 and 124-28).[64,65] In the knee, the femoral area adjacent to the intercondylar region is the site most frequently invaded as the tumor grows along the cruciate ligamentous insertions. Periarticular osteopenia, periosteal reactions, and joint destruction are unusual because the joint space is preserved until late in the course of the disease.[68,69] The radiographic differential diagnosis of a given case includes (1) tuberculosis, which generally involves more osteopenia and joint destruction; (2) hemophilia, which is also associated with more extensive joint destruction; (3) synovial chondromatosis, which frequently has calcified radiopaque bodies; and (4) rheumatoid arthritis, which shows more severe osteopenia and joint narrowing.

Grossly, the synovium in diffuse tenosynovial giant cell tumor is red-brown to mottled orange-yellow and looks like a plush Angora rug (Figure 124-29). Matted masses of villous projections and synovial folds are prominent and are admixed with rubbery-to-soft nodules (0.5 to 2 cm in diameter) that are sessile or pedunculated. The synovial membrane is thick and succulent and is often coated with a fibrinous exudate. Red-brown or golden brown tissue may extend deep into subsynovial structures or may invade the joint capsule. If a tendon sheath is involved, a sausage-shaped mass may be evident because the sheath is distended by the proliferating tumor. If the joint capsule is invaded, adjacent soft tissue structures, including nerves and vessels, may be covered by wispy, red-brown tissue. If soft tissue invasion is extensive, the lesion may appear as a soft-to-rubbery, red-brown mass with foci of hemorrhagic cysts. Similar tissue may be present near the chondro-osseous junction or may be wrapped around vascular and ligamentous attachments to bone surfaces, which represent entrance points into the interior of the bone. Although other conditions, such as hemochromatosis and hemosiderosis, also may discolor the synovium brown, the nodular component is usually absent; in addition, microscopic features are definitive for separating these entities (discussed in a subsequent section).

Microscopic examination reveals marked synovial cell hyperplasia with surface proliferation and, more importantly, subsynovial invasion by masses of mitotically active polygonal or round tumor cells with moderate amounts of eosinophilic cytoplasm and round nuclei (Figures 124-30 and 124-31). Included among the invading tumor cells are scattered lymphocytes, multinucleated giant cells (osteoclast, Touton, or foreign body type), hemosiderin-laden macrophages, and fibroblasts. Hemosiderin is usually present and can be located in the stroma or the cytoplasm of synovial lining cells, macrophages, and tumor cells. Foci of hemorrhage are common and are surrounded peripherally by giant cells and macrophages (Figure 124-32). Scattered collections of foamy macrophages (xanthoma cells) filled with

lipid also are a frequent finding. These different cell populations fill and distend the synovial villi, causing them to fuse with adjacent ones, forming nodules. In some nodules, abundant collagen deposition with hyalinization may cause confusion with neoplastic bone. Rarely, the tumor may contain focally calcified cartilaginous matrix.[71]

Immunohistochemical studies have been interpreted to support a synovial cell or fibrohistiocytic phenotype of the neoplastic cells.[37,70] The tumor cells express clusterin and D2-40, and a minority of large cells stain with antibodies to desmin.[72] It is important to note that the cells that harbor the translocation express CSF1. Flow cytometric analyses have shown that some of these tumors, especially tumors that have large extra-articular soft tissue components, may be aneuploid and have high proliferative indices.[62] Although these flow cytometric findings may help predict which cases would be more locally aggressive, examples of diffuse tenosynovial cell tumors with these attributes have not metastasized.[62]

Treatment of diffuse tenosynovial giant cell tumor of the joint is not standardized and has included radiation therapy, total synovectomy, isotopic synoviorthesis, arthrodesis, bone grafting, and primary arthroplasty.[58,60,73] Although no single therapy has been consistently successful, wide synovectomy is currently the recommended treatment.[58,60,74] It is difficult to perform an actual complete synovectomy, however; residual involved synovium frequently remains, causing a local recurrence rate of 16% to 48%.[75,76] A macroscopically incomplete tumor resection is associated with a more than twofold increased risk for tumor recurrence compared with a macroscopically complete resection.[74] Tumors arising in the knee have a higher rate of recurrence compared with tumors arising in other joints. Rarely, recurrent disease or tumors with large extra-articular components may require more radical surgery, such as ray resection or amputation.[62] Studies have shown that moderate doses of radiation may control disease and even cure patients with such extensive disease, possibly obviating the need for radical surgery or amputation.[77] Finally, drugs targeting the CSF1 pathway are being tested to determine their efficacy in clinically challenging cases.[78] Imatinib mesylate is a tyrosine kinase inhibitor (TKI) with activity against CSFR1, and early studies have shown success in the treatment of progressive or relapsing diffuse tenosynovial giant cell tumor of the joint.[79] Phase II clinical trials with nilotinib, a TKI with similar activity against CSF1R, are currently ongoing.[79] Heterogeneity of tumor responses between different TKI agents has been documented and underscores the need for a better understanding of the associated molecular and genetic mechanisms.[80] Similar targeted approaches are being tested with monoclonal antibodies such as MCS110, a humanized monoclonal antibody directed against CSF1, and RG7115, a monoclonal antibody that inhibits the dimerization of CSFR1; both are currently being investigated in clinical trials.[74]

### Malignant Diffuse Tenosynovial Giant Cell Tumor

Malignant tenosynovial giant cell tumors are rare; only a handful of cases have been reported.[81-83] The knee is the most commonly affected joint, and in many cases, a

co-existing benign-appearing, diffuse tenosynovial giant cell tumor is noted. In the malignant variant, the neoplastic cells may be spindle or polyhedral shaped and cytologically malignant. These tumors have the capacity to behave aggressively; almost 50% of patients die from metastatic disease.[81] Trisomies involving chromosomes 5 and 7 have been reported.[84]

### Localized Tenosynovial Giant Cell Tumor of the Joint (Benign Giant Cell Synovioma, Benign Synovioma, and Localized Nodular Synovitis)

A localized tenosynovial giant cell tumor of the joint manifests as a solitary, well-circumscribed mass. It usually consists of a single sessile or pedunculated, sometimes lobulated, tumor that ranges from 1 to 8 cm in diameter (Figure 124-33). Most commonly, it is unilateral, arises in the knee, and is equally distributed between the sexes.[85]

Symptoms are similar to those of diffuse tenosynovial giant cell tumor, except that in the localized variant, a higher frequency of joint locking is reported because the mass interferes with motion.[85] A few patients may present with acute severe joint pain caused by torsion and infarction of the tumor. Effusions are common, but the synovial fluid tends to be less bloody than in the diffuse variant, and it may be clear.

Imaging studies show a heterogeneous nodular mass that contains lipid and hemosiderin deposits (Figure 124-34). In the knee joint, the tumor frequently arises in the suprapatellar notch, in the femoral notch, and between the meniscus and the joint capsule.[85] Usually, no bone invasion occurs. Marginal excision is generally curative. Small lesions can be extirpated arthroscopically.[85]

Histologically, localized tenosynovial giant cell tumor of the joint is identical to the nodules of the diffuse variant. The main difference is that the prominent synovial villi present in the diffuse variant are absent or sparse.

### Localized Tenosynovial Giant Cell Tumor of the Tendon Sheath (Giant Cell Tumor of the Tendon Sheath and Fibroxanthoma of the Tendon Sheath)

Localized tenosynovial giant cell tumors of the tendon sheath usually involve the hand or wrist and less frequently the foot or ankle.[59] They are the most common soft tissue tumor of the hand and usually arise from the flexor tendon sheaths of the finger; the index finger is affected most frequently, followed in descending order of frequency by the third, fourth, fifth, and first fingers.

Tumors of the digits predominate in females, with a male-to-female ratio of at least 2:1[59,86]; tumors of the toes have an equal sex distribution.[59] On average, patients are in the third to fifth decades of life and present with a painless, palpable, firm, mobile mass.

Clinically, the mass usually is solitary and is located on the flexor surface, but it may bulge into the extensor or lateral aspects of the digits (Figure 124-35). The tumors are slow growing, and the intervals between detection and surgical treatment have ranged from several weeks to longer than a decade, with an average interval of slightly longer than 2 years.[59,86]

Radiographically, the tumors appear as well-circumscribed soft tissue masses, and in about 25% of cases, adjacent extrinsic excavation of the cortical bone has a sclerotic margin (Figure 124-36).[59,86] MRI reveals that the lesions have a hypointense signal on T1-weighted images and either a hypointense or a hyperintense signal on T2-weighted images. These findings are helpful in distinguishing giant cell tumors of the tendon sheath from other soft tissue tumors.[87]

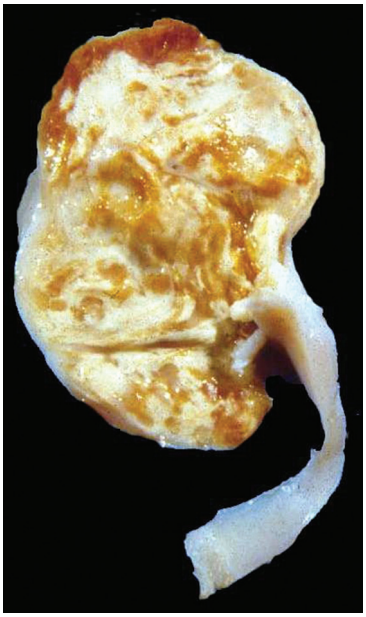

**Figure 124-33** A localized tenosynovial giant cell tumor of the joint with attached pedicle. The mass is well circumscribed and brown-yellow.

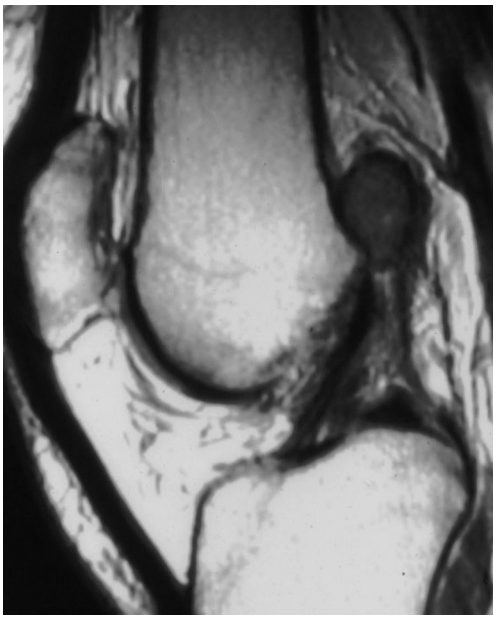

**Figure 124-34** MRI shows a well-delineated dark mass in the posterior knee joint.

**Figure 124-35** A tenosynovial giant cell tumor manifesting as a mobile, solid, firm mass.

**Figure 124-36** The cortex of the phalanx is eroded by the tenosynovial giant cell tumor.

The gross pathologic findings are of a well-circumscribed, multinodular, round, rubbery, variegated red-brown-tan-yellow mass, generally not larger than 5 cm in diameter, which is firmly attached but easily peeled off the involved tendon (Figure 124-37). At surgery, the lesion sometimes may "pop out" of the incision. The cut surface reveals a solid mass that ranges from hues of yellow to orange-red-brown, depending on the quantity of lipid and blood pigments present. Often bands or septa of white fibrous tissue subcompartmentalize the lesion. The structure and immunophenotype of the cell types present are identical to those in the diffuse variant (Figure 124-38).[72,88] Ultrastructurally,

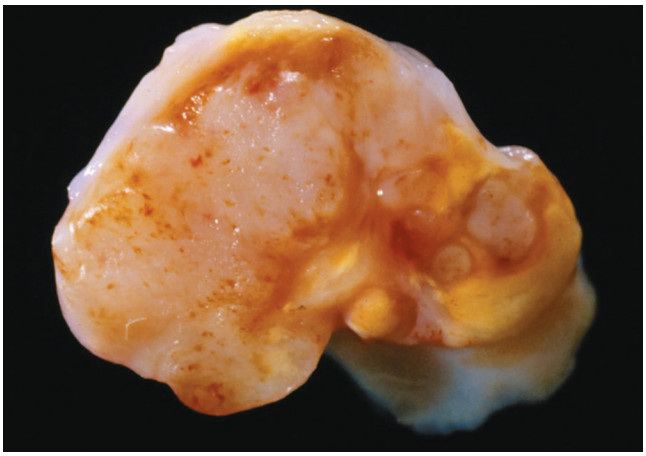

**Figure 124-37** A well-delineated, white-yellow, and focally brown tenosynovial giant cell tumor.

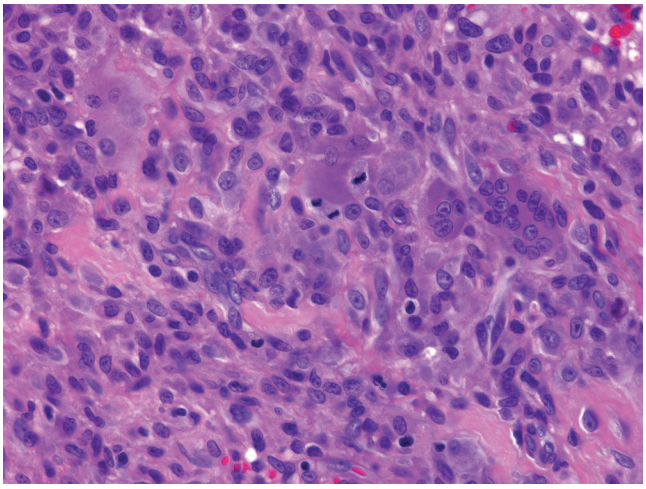

**Figure 124-38** Mitotically active polyhedral cells and scattered osteoclast-type giant cells in a tenosynovial giant cell tumor.

proliferating cells have features similar to type A and type B synovial lining cells.[86-89] Flow cytometry has been performed in a few cases, and all have been diploid.[62] Cytogenetic studies show that many of these tumors have a translocation between 1p13 and 2q35.[54,55,90]

These tumors are benign and do not metastasize. Malignant giant cell tumors of the tendon sheath have rarely been reported.[81,91] The treatment of choice is conservative surgical excision, which is usually curative. Local recurrence may be noted if excision is incomplete.[59,86]

## MALIGNANT TUMORS OF THE JOINT

Malignant tumors of joints are uncommon and are classified into primary and secondary types. Primary malignancies are virtually always sarcomas and usually arise within the synovium of large diarthrodial joints, especially the knee. Patients are adults who present with chronic symptoms of pain, swelling, and effusion, and most tumors are chondrosarcomas or synovial sarcomas. Rarely, other sarcomas originate within a joint; our experience has included cases of intra-articular myxoinflammatory fibroblastic sarcoma,

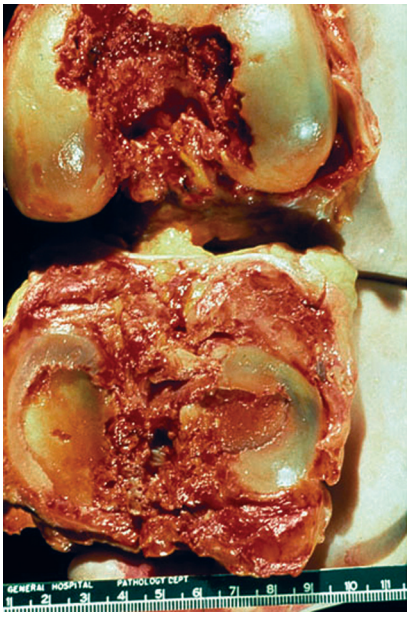

**Figure 124-39** Angiosarcoma of synovium of the knee joint. The hemorrhagic tumor erodes into the distal femur and proximal tibia.

pleomorphic fibrosarcoma, extraskeletal myxoid chondrosarcoma, conventional chondrosarcoma, malignant tenosynovial giant cell tumor, and angiosarcoma (Figure 124-39). Epithelioid sarcoma is another primary sarcoma that has been reported to arise from the joint exceptionally rarely.[92] Secondary malignant tumors of joints, by definition, originate beyond the confines of the joint; most are sarcomas that extend from neighboring bone or surrounding soft tissue. Although synovial tissue is highly vascular, metastases or involvement of the synovium by carcinoma, lymphoma, or leukemia is uncommon.

## Primary Sarcomas of Joints

### Conventional Chondrosarcoma

Conventional chondrosarcoma arising in the synovium is unusual; fewer than 100 cases have been reported in the English language.[43-46,82,93] In approximately 50% of cases, the chondrosarcoma arises in association with pre-existing synovial chondromatosis, and investigators studying a large series of synovial chondromatosis reported malignant transformation into chondrosarcoma in 6.4% of cases.[43,45-47,93,94] Patients are usually in the fifth to seventh decade of life, and distribution between the sexes is equal.[93] Typically, the tumor manifests as a progressively enlarging joint mass that may cause mechanical dysfunction, pain, and stiffness. In patients who have pre-existing synovial chondromatosis, the duration of symptoms is usually long, and in some instances, symptoms may be present for 25 years.[43,93] Most chondrosarcomas arise in the knee joint, followed by the hip and elbow joints.

Radiographic studies usually show a periarticular soft tissue mass that may have dense irregular or ring-like calcifications. Occasionally, invasion into the medullary cavity of adjacent bone is evident. The radiographic differential diagnosis varies according to the presence of calcification and includes synovial chondromatosis, synovial sarcoma, diffuse tenosynovial giant cell tumor, and chronic synovitis.[93]

Grossly, the involved joint is filled with synovium massively thickened by innumerable nodules of opalescent blue-white cartilage. The nodules of cartilage vary in size and may be free-floating in the joint cavity. In several cases, the tumor has extended into adjacent soft tissue and bone.

Microscopically, the tumor is composed of malignant hyaline and myxoid cartilage. Rarely, the matrix is entirely myxoid and has features of extraskeletal myxoid chondrosarcoma.[94] The neoplastic cartilage is cellular and contains cytologically atypical chondrocytes. The periphery of the lobules of cartilage is usually the most cellular, and in this region, some of the tumor cells can be spindled. Other findings include necrosis and permeation of invaded bone.[93] Coexisting synovial chondromatosis can be identified by its well-formed nodules of hyaline cartilage, which are less cellular, containing cytologically banal-appearing chondrocytes and a matrix that is frequently mineralized.

Treatment is usually surgical extirpation with consideration given for chemotherapy in high-grade lesions or lesions that have metastasized. Inadequate surgical removal virtually ensures local recurrence, which may necessitate subsequent radical excision. Metastases have occurred in approximately one-third of reported patients; the lung is the most common site for systemic spread.[43,93]

### Synovial Sarcoma

Synovial sarcoma is a common sarcoma that accounts for approximately 6% to 10% of soft tissue sarcomas. It usually develops in the deep soft tissues and rarely arises in joints (Figure 124-40), but it may secondarily invade articular synovium from neighboring soft tissues. Earlier descriptions of this tumor attest to its wide spectrum of structure because such names as *adenosarcoma* and *synovial fibrosarcoma* were used until the term *synovial sarcoma*, first introduced in 1936, became commonplace. The structure of synovial sarcoma mimics a joint in its early stage of development in that it contains cleft-like spaces and glands delineated by large polygonal (epithelioid) cells surrounded by fascicles of spindle cells. The clefts and glands simulate a microscopic "joint space" that is bounded by synovial lining cells and is supported by subsynovial mesenchymal cells. Because epithelial or spindle cells may predominate, synovial sarcoma has been subtyped into biphasic and monophasic spindle cell and epithelial types, although the last type is exceptionally rare.

Synovial sarcoma commonly affects adolescents and young adults. In a series of 121 cases, the age range was 9 to 74 years, with a median age of 34 years; however, it occurs in children with significant frequency.[95,96]

The term *synovial sarcoma* implies that the tumor originates from the synovium; however, fewer than 10% of cases are intra-articular or show continuity with a synovial lining.[97,98] The cell of origin is thought to be an immature mesenchymal progenitor cell that is thus far incompletely characterized.[99]

Approximately 60% to 70% of synovial sarcomas arise in the extremities, especially the lower limb, in the vicinity of large joints, particularly the popliteal areas of the knee

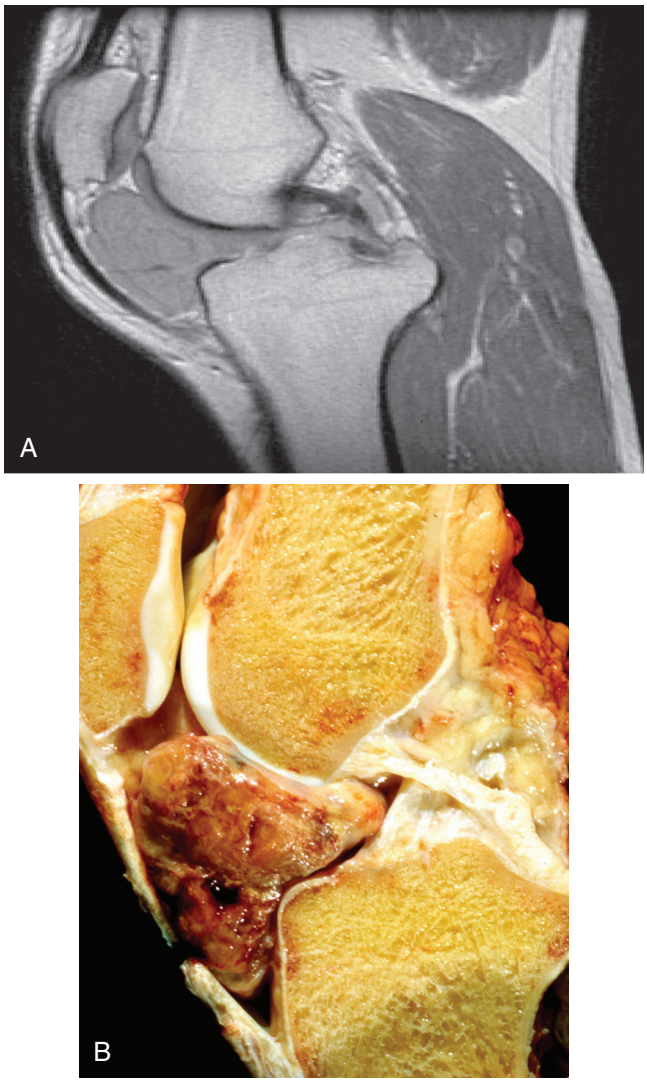

**Figure 124-40** **A,** MRI of a rare example of intra-articular synovial sarcoma. The infrapatellar tumor is well circumscribed and has a focal inhomogeneous appearance. **B,** The gross specimen shows that the tan, hemorrhagic tumor bulges into the joint but is covered by synovium.

and foot.[100,101] Regions of the thigh, hand, leg, and digits may be affected, and in the distal extremities, tumors are often adjacent to joint capsules, tendon sheaths, or both. Tumors also have been reported in the neck, torso, craniofacial region, retropharyngeal space, retroperitoneum, spermatic cord, orbit, tongue, mediastinum, soft palate, heart, liver, kidney, lung, pleura, and prostate.

No clinical features specific to synovial sarcoma distinguish it from other sarcomas. The most common presentation is the development of a slowly enlarging, deep-seated, palpable mass that is painful in about 50% of cases.[96,101] Symptoms may be present for an unusually long time, ranging from months to 25 years, with an average of about 6 months to 2.5 years, before medical evaluation is sought.[96,101] Delay in diagnosis is more frequent with tumors that are located in the deep soft tissues than in tumors that are based in the more superficial and clinically noticeable regions. In some cases involving the knee region, vague mild pain over several months may occur before a mass is appreciated, and if the tumor reaches a large size, limitation of motion finally may be noted. Head and neck lesions produce symptoms related to their specific sites, such as hoarseness and breathing or swallowing difficulties. Rarely, a patient may present with a symptom resulting from pulmonary metastasis, such as hemoptysis.[101]

Classically, plain film findings of synovial sarcoma consist of a well-circumscribed, deep-seated, soft tissue mass. Synovial sarcoma is one of the few primary soft tissue tumors that frequently calcify. Approximately 30% to 50% of cases reveal radiographically detectable calcifications that may have a fine, stippled, or dense appearance (Figure 124-41).[102] The calcification may be focal or may present throughout most of the tumor.[103] Periosteal reaction of adjacent bone is elicited in approximately 20% of cases, but bone is rarely invaded by the tumor.

CT is more sensitive than plain radiography in showing calcification or periosteal reaction. MRI is important in delineating the anatomic extent of the tumor and usually shows a large inhomogeneous mass with areas of hemorrhage. The radiographic differential diagnosis includes

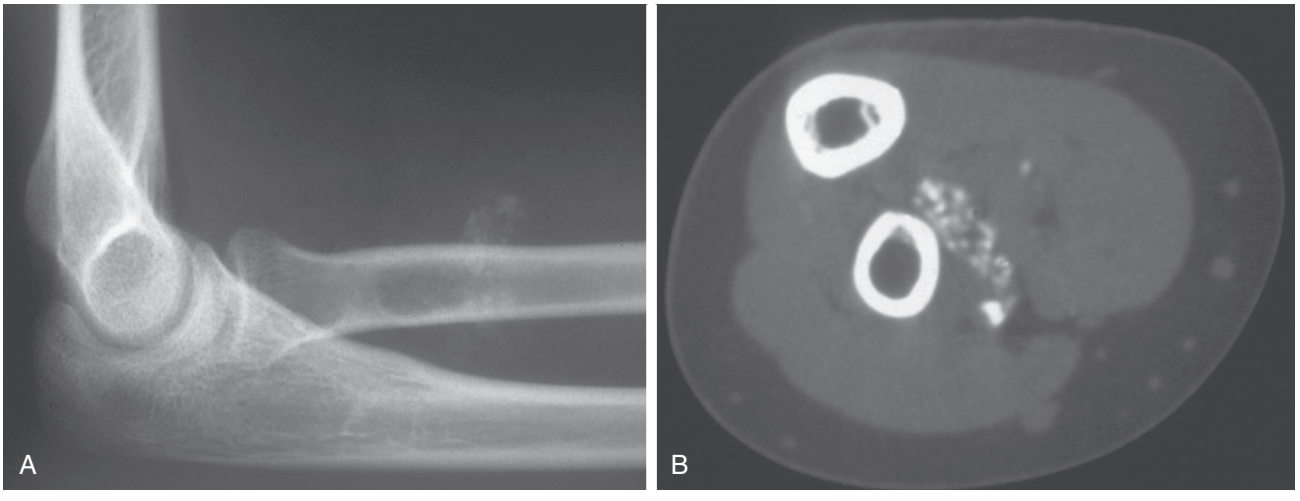

**Figure 124-41** **A,** Focally mineralized synovial sarcoma in the deep soft tissues in the vicinity of the elbow joint. **B,** An axial computed tomography scan shows intratumoral calcification.

hemangioma, lipoma, synovial chondromatosis, soft tissue chondrosarcoma or osteosarcoma, myositis ossificans, aneurysm, and other sarcomas.

The gross pathologic findings of synovial sarcoma reveal a well-demarcated, pink-tan, fleshy mass that easily detaches or "shells out" from its tumor bed (Figure 124-40B). The cut surface is usually uniform, gray-yellow, and rubbery. Calcified areas are gritty and hard. In larger tumors, areas of hemorrhage, necrosis, or both with cystification and gelatinous breakdown of tissue may be seen. A synovial sarcoma sometimes grows between tendons, muscles, and fascial planes or wraps around neurovascular bundles.

Synovial sarcoma is subtyped into three patterns on the basis of predominant microscopic findings: monophasic spindle cell, monophasic epithelial, and biphasic variants. Use of such a classification system requires some subjectivity because many of these tumors have a variable histologic picture. A useful differential observation is that marked cellular pleomorphism and atypia usually are not present in synovial sarcoma and, when observed, tend to point to some other type of neoplasm, such as a pleomorphic fibrosarcoma or an undifferentiated pleomorphic sarcoma.

Microscopically, the hallmark of the more common biphasic synovial sarcoma is the two different populations of neoplastic cells consisting of epithelial and spindle cells (Figure 124-42). Epithelial cells may be cuboidal or columnar and, similar to true epithelium, may have well-defined cytoplasmic borders. These cells may form glandular spaces, line papillae or cleft-like spaces, or grow in cohesive groups (see Figure 124-42). Epithelial cells usually are surrounded by fascicles of uniform, small, and plump spindle cells. Spindle cell fascicles are densely cellular and frequently are arranged in a "herringbone" pattern. In most biphasic synovial sarcomas, the spindle cell component predominates, and calcification of hyalinized stroma most frequently occurs in spindle cell regions. Some tumors may show bone formation, which may be present in spindle or epithelial areas. In the monophasic variants, spindle or epithelial cells may be the only recognizable component (Figure 124-43; also see Figure 124-42).

Immunohistochemistry has shown that epithelial and the spindle cell components frequently stain with antibodies to keratin and epithelial membrane antigen, which usually indicates an association with epithelial neoplasms.[104-106] This pattern of reactivity has helped make it possible to separate synovial sarcomas from morphologically similar tumors, such as fibrosarcomas and malignant peripheral nerve sheath tumors.[106] It has also provided evidence that synovial sarcoma does not arise from or recapitulate the synovium, because normal synovial cells do not stain with these antibodies.[107]

Cytogenetic studies of synovial sarcomas have detected a consistent translocation of t(X;18)(p11.2;q11.2) in almost all cases, regardless of whether the tumor is biphasic or monophasic.[100,108] This finding provides insight into the genesis of synovial sarcoma, which is thought to be related to dysregulation of transcription and can be used as a diagnostic feature. This characteristic translocation leads to the fusion of the SWI/SNF chromatin remodeling complex subunit *SS18* to the C-terminal repression domains of *SSX1* or *SSX2*, disrupting epigenetic control and acting as the central genetic "driver" in this tumor.[99] No relationship between the location of the translocation breakpoint and the prognosis has been discerned.

The prognosis of synovial sarcoma is poor. In one study of 150 patients with nonmetastatic disease, 5-year, 10-year, and 15-year disease-free survival rates were 59%, 52%, and 52%, respectively.[103] Many factors influence prognosis; tumors that are small (<5 cm), arise in patients younger than 25 years, and lack poorly differentiated areas have a high rate of cure.[96] In contrast, large tumors (≥5 cm) that arise in patients 25 years or older and that contain poorly differentiated areas have a dismal outcome.[96] The impact of histologic subtype has been controversial.

The natural history of synovial sarcoma consists of local recurrence, which may be repetitive. Most recurrences manifest within 2 years after initial treatment, but intervals longer than 10 years are not exceptional. Ultimately, metastases occur in many patients, with the lungs the most common site; regional lymph node involvement has been

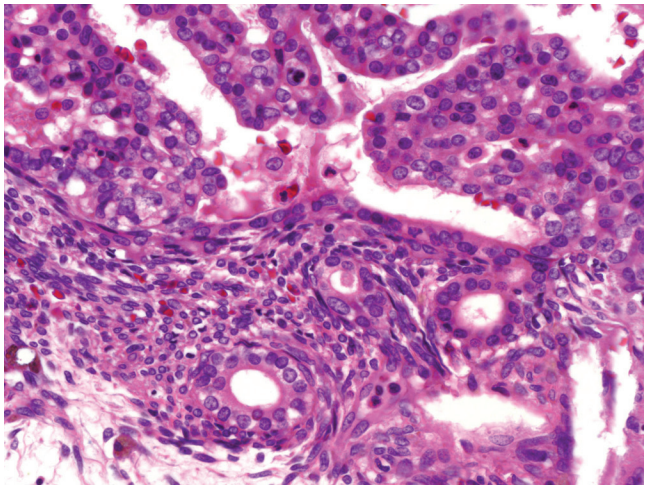

**Figure 124-42** A biphasic synovial sarcoma with epithelial cells forming glands and papillary structures. The spindle cell component surrounds the glands.

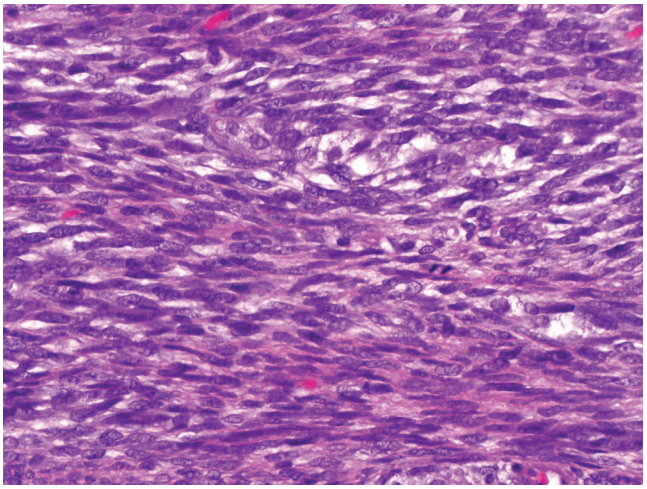

**Figure 124-43** A monophasic spindle cell variant of synovial sarcoma with the fascicles of tumor cells forming a herringbone pattern.

reported in a few patients.[109] About 10% of patients die within 1 year after diagnosis with metastatic disease, and 90% of these patients have massive pulmonary metastases.

Treatment must contend with issues involved with local and systemic therapy. Successful local control usually can be achieved through limb salvage surgery combined with radiation.[109,110] Because regional lymph nodes may be involved, their status should be evaluated carefully, and if enlarged, they should be treated. Systemic treatment consists of various chemotherapy regimens that have provided questionable benefit, although adjuvant chemotherapy usually is recommended for patients who are at high risk—that is, patients with tumors larger than 5 cm.[111]

## Secondary Malignant Tumors of the Joint

### Sarcomas

Primary sarcomas of bone, such as osteosarcoma and chondrosarcoma, infrequently involve a joint because intact articular cartilage usually acts as a barrier to direct tumor extension. However, when it is observed, joint invasion usually occurs via a pathway created by a transarticular fracture, via growth along tendoligamentous structures, or through capsule insertion sites. Because of this circumstance, on histologic grounds alone it may be difficult to distinguish some forms of synovial chondromatosis from a low-grade intraosseous chondrosarcoma that has secondarily spread into the joint.

Similarly, primary soft tissue sarcomas gain access into the interior of a joint by growing through the joint capsule in conduits occupied by pre-existing vascular structures or along tendons and ligaments. This complication can make providing adequate therapy challenging because treatment may require en bloc resection of the joint.

### Metastatic Carcinoma

The synovium, in contrast to other richly vascular tissues, is rarely the site of metastatic carcinoma; this may reflect the fact that only clinical cases in which joint symptoms prevail are reported, because at autopsy, joints are not routinely examined. Most carcinomas that metastasize to the synovium originate in the lung, followed by the gastrointestinal tract and breast.[112-114] Affected patients are usually elderly, and the knee is the most frequently involved joint. In many reported cases, the underlying bone also contains metastatic deposits.

## Malignant Lymphoproliferative Disease

The various types of malignant lymphoproliferative diseases, including leukemia, lymphoma, and myeloma, can involve the synovium and may produce osteoarticular symptoms.[115-117] This complication occurs most frequently in individuals with leukemia and is seen in both acute and chronic forms.[117] Joint symptoms have been observed in 12% to 65% of children and in 4% to 13% of adults with leukemia.[117] Arthritis can develop at any time during the disease course and can be the presenting symptom. Large joints are affected more commonly than are small joints, and the arthritis is often pauciarticular, asymmetric, migratory, and severe. Symptoms may result from leukemic infiltration of the synovium or irritation of the neighboring periosteum. When arthritis is the major presenting symptom, it may cause confusion with septic arthritis, rheumatic fever, subacute bacterial endocarditis, or rheumatoid arthritis.

## C

C5a receptor, 359
C12C antibody, 56
Cachectin, 52
Cachexia, HIV and, 1933
CACP syndrome. *see* Camptodactyly-arthropathy-coxa vara-pericarditis (CACP) syndrome
Cadherins
as cell adhesion molecules, 386
in extra-cellular matrix, 235
in synovial fibroblasts, 23
Cadherin-11, 7, 9
in organ integrity, 238-239
from rheumatoid arthritis, 23
Caffeine, rheumatoid arthritis and, 1109
CAIA. *see* Collagen antibody-induced arthritis (CAIA)
Calcaneus tendon (Achilles tendon), 602-603
posterior joint pain origin, 737
tophi in, 1627, 1628*f*
Calcific shoulder tendonitis, 2039
Calcific tendinitis, 681-682
incidence of, 681
Calcineurin, inhibitors, 1373-1374
Calcinosis
in juvenile dermatomyositis, 1852, 1853*f*
severity of, 1470-1471
Calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias (CREST), 824-825
syndrome, 1426
Calcitonin
for osteoporosis, 1738-1739
for Paget's disease, 1747
parenteral, adverse effects of, 1739
Calcium
in cellular activation, 195-196
channel blocker, extended-release formulation, 1434-1435
crystals, presence of, 1690
hydroxyapatite crystals, clumps of, 788*f*
mineralization-regulating effects of, 1647
for osteoporosis, 1737
requirements for, NAS recommendations, 1737*t*
Calcium flux, 413
Calcium phosphate crystal
arthropathies of, 1662
chalky, 1652.*e1f*
deposition of, differential diagnostic considerations, 1658-1659
Calcium pyrophosphate dihydrate
American College of Rheumatology and European League Against Rheumatism diagnostic criteria for, 1646*t*
arthropathy, radiographic features of, 1654*f*
crystals
detection of, 1645
formation of, promotion by adenosine triphosphate, 1647
identification, 607
presence of, 787-788, 788*f*
ultrasound, limitation, 1659-1661
detection
dual-energy CT in, 1661
sensitivity, of cytocentrifugation, 1661
secondary to primary metabolic disorders, 1650
treatment of, 1661-1663
algorithm for, 1658*f*
future directions in, 1662-1663
Calcium pyrophosphate dihydrate crystal deposition
arthropathy of, 1651*f*
idiopathic symmetric pseudorheumatoid, 1653.*e2f*
concentrated, 1655
diagnostic criteria, high-resolution ultrasound in, 1659-1661, 1659*t*, 1660*f*
tumoral, 1659.*e1f*
Calcium pyrophosphate dihydrate crystal deposition disease (CPPD), 1652-1653, 1661-1662
aging-associated, sporadic, 1648-1649
causes of, 1652*t*
chondrocalcinosis, 1655*f*
clinical features of, 1652-1656
clinical forms of, 1655
clinical manifestations of, 1653
clinical presentations of, 1653*t*
computed tomography in, 873
conventional radiography in, 866, 868*f*
detection, high-resolution ultrasound in, 1659-1661, 1659*t*, 1660*f*
diagnosis and diagnostic tests for, 1656-1661
algorithm, 1658*f*
use of plain radiographs in, 1659
differential diagnosis of, 1657-1658
epidemiology of, 1645-1646
evaluation of, algorithm for, 1658*f*
familial, 1646-1647, 1655-1656
genetics of, 1646-1647
high-resolution ultrasound and advanced imaging for, 1659-1661, 1660*f*
hydroxychloroquine for, 1662
laboratory diagnostic test for, 1661
magnetic resonance imaging in, 887
outcome/prognosis of, 1663
Calcium pyrophosphate dihydrate crystal deposition disease (CPPD *(Continued)*
pathogenesis of, 1647-1652
prevalence of, 1646
therapeutics for, 1662*t*
treatment of, 1661-1663
algorithm for, 1658*f*
future directions in, 1662-1663
ultrasonography in, 896*f*, 897
Calpains, 107
Calpastatin, 114-115, 114*t*
CaMKII, 93
Camptodactyly-arthropathy-coxa vara-pericarditis (CACP) syndrome, 28, 29*f*, 784

Cytokines, 396-407, 851, 851*t*, 1299
  in acute inflammation, 400
  alteration in SLE, 1338-1339
  alternative processing pathways for, 400
  antagonists, 1149-1150
  BAFF family of, 213, 214*f*
  cellular interactions across diverse tissues by, 405-406
  in chronic inflammation, 404-406
    agonist/antagonist, 405
    release in, 406
  classification of, 396
  as disease-modifying anti-rheumatic drugs, 405

Cytokines *(Continued)*
effector function of, 400-406
effects beyond immune regulation, 406
enzymatic activation of, 399-400
expression of, regulation of, 398-400
fibroblast, 1145-1151
function of, in vitro and in vivo, 396-397
glucocorticoids and, 937, 942*f*
as granule contents, 254-255
immunosuppressive, 1149-1150
inflammatory process and, 1963-1964
innate immune responses of, 284
juvenile idiopathic arthritis and, 1816, 1817*t*, 1818-1819
macrophage-derived, in sarcoidosis, 1985
as mechanistic biomarkers, 514
miscellaneous, 403*t*
networks, 52
in synovitis, 1150-1151, 1150*f*
as newly synthesized mediators, 255
in platelet production, 265
pre-formed, 255
production of, 179
receptors, 397-398, 397*f*
class I, 409
class II, 409
enzymatic activity of, 409-411
signaling pathways through, 413*f*
soluble, 1150
regulation of
post-transcriptional, 399
signaling and, 398*f*
in T cells, 402*t*
transcriptional, 399
regulatory function of, 399*f*
in rheumatoid arthritis, 1118-1119
role of, 405
scleroderma and, 1417-1419
in spondyloarthritis, 1251
synovial, in rheumatoid arthritis, 1143*t*
in synovial B cells, 1135
T cells, 1142-1145
effector function of, 401*t*
T helper cell
imbalance, in rheumatoid arthritis, 1144-1145
type 1, 1143-1144
type 2, 1144
type 17, 1144
Cytolytic T lymphocyte-associated protein 4 (CTLA-4), 198, 1962
extra-cellular portion of, 1031
Cytomegalovirus (CMV), viral triggers, 1225-1226
Cytosol, protein degradation in, 1492*f*
Cytosolic receptors, 155-156
Cytotoxic therapy, 1370-1372
indications for, 1371*t*
Cytoxan, 1734

## D

Dacryoadenitis, in $IgG_4$-related disease, 2030*f*
Dactylitis, 1289-1290
in sickle cell anemia, 2020-2021
DAH. *see* Diffuse alveolar hemorrhage (DAH)
Damage-associated endogenous TLR ligands, 1419
Damage/danger-associated molecular patterns (DAMPs), 44*f*, 156-158, 276
biomarkers and, 516-517
for innate immune recognition, 276-281
DAMPs. *see* Damage/danger-associated molecular patterns (DAMPs)
DANCER trial. *see* Dose-ranging Assessment: International Clinical Evaluation of Rituximab in RA (DANCER) trial
Dance-related injuries, incidence, 529
Dancers
injuries, distribution, 529
musculoskeletal disorders, 529-530
Danger signals, source of, mitochondria as, 322
Dantrolene, 1091, 1091*f*
DAPSA. *see* Disease Activity Index for Psoriatic Arthritis (DAPSA)
DAS. *see* Disease Activity Score (DAS)
Dasatinib, 1455-1456
da Vinci, Leonardo, 78
DCAT. *see* Double-contrast arthrotomography (DCAT)
DCPD. *see* Dicalcium phosphate dihydrate (DCPD)
DCs. *see* Dendritic cells (DCs)

Death-inducing signaling complex (DISC), 422
activation platform for procaspase-8, 422
Debranching enzyme deficiency, 1603
Decay-accelerating factor, 306
Decernonitib. *see* VX509
Decompressive laminectomy, alternative, 713
Decorin, 12, 38-39
degradation of, 119-120
Dectin-1, 277-278
Deep heat applications, 567
Deep perivascular lymphocytic infiltrate, 1233-1234
Deep tendon stretch reflexes, performing/grading, 664
Defective interfering (DI) particles, 1951
Defective tolerance, 309-310
Defensins, 171-172
Deferiprone, for thalassemia, 2023-2024
Deferoxamine chelation, for thalassemia, 2023-2024
Deficiency interleukin-1 (IL-1) receptor antagonist (DIRA), 1681-1682
Deflazacort, 948
Deformability, of synovium, 27
Deformity, observation of, 590
Degenerative arthritis, 617
manifestation of, 657
physical activity, impact, 524
Degenerative cartilage disease, CPPD crystal deposition disease, associated with sporadic CPPD, 1654
Degenerative enzymes, n-3 fatty acids on, 1097
Degenerative joint disease, 1685
impact, 762
Degenerative spondylolisthesis, development, 703-704, 705*f*
Degos disease, 1341
Degrees of freedom, 79
Dehydration
in gout, 1110
volume depletion, 1607
Delayed gadolinium-enhanced MRI of cartilage (dGEMRIC), 1713
Demargination, 185
Demyelinating disease, impact, 651
Demyelinating syndromes, tumor necrosis factor inhibitors and, 1009
Dendritic cells (DCs), 126-144
antigen presentation of, 134-136
autoimmunity and, 138-141
autophagy and, 131
B cell activation and, 136-137
B cell homing as, 215
$CD1c^+$/BDCA-$1^+$, 129
$CD14^+$, 128-129
$CD141^{++}$/BDCA-$3^+$, 129
circulating, 129
tissue resident, 128-129
conventional, 127-130
co-stimulation in, 142
dermal, 128-129
$CD1a^+$, 129
development of, 130-137
differentiation of, 1523-1524
follicular, B cells and, 221, 221*f*
future directions for, 141-142
immune dysregulation of, 1413
immune response activation in, 142
immunologic synapse and, antigen-specific interactions in, 291
inflammation resolution in, 141-142
inflammatory monocyte-derived, 129
juvenile idiopathic arthritis and, 1820
life history/heterogeneity of, 147-150
lipid presentation of, 135-136
in lymphoid tissue, 151*f*
lymphoid tissue-associated, 130
maturation of, 130-134, 150-152, 151*f*
homeostatic, 131
pattern-recognition receptors and, 131-134
Toll-like receptors and, 131-132
metabolism of, 319-320
migration to mesenteric lymph nodes, 294
monocyte-derived, 145-146
maturation markers for, 151*t*
myeloid, 145
natural killer cell activation and, 137
Peyer's patch, role of, 1314*f*
phagocytosis and, 131
plasmacytoid, 129-130, 145-146
in psoriasis, 138-139
in rheumatoid arthritis, 140-141, 1136-1137
role of, 127*f*
in Sjögren's syndrome, 141
structures of, 296*f*
subsets of, 126-130
synovial sublining macrophages, usage, 796-797
in systemic lupus erythematosus, 139-140
T cell activation and, 136
T cell imprinting and, 296-297
tolerance and, 137-138
Denosumab
administration of, 1740
osteonecrosis of jaw and, 1767
Dental caries, xerostomia and, 1240
Dentinogenesis imperfecta (DI), 1805
Depression, 710
Dermal dendritic cells, 128-129
$CD1a^+$, 129

Dermatomes
distribution of, 663, 664*f*
pain, 663
Dermatomyositis (DM), 541, 632-633, 633*f*, 817
adult patients, treatment algorithms for, 1483*f*
amyopathic, 1473
Bohan and Peter criteria for, 1475*t*
juvenile, 1473
malignancy and, 2054, 2054*f*
management of, 1483-1485
microarrays and, 1469
microvessel involvement of, observation of, 1468-1469
occurrence, 550
outcome of, 1483-1485
peripheral blood phenotyping in, 1855
pharmacologic treatment of, 1483-1484
polymyositis and, 1469-1473
sine myositis, 632
skin changes in, characteristics of, 1470*f*-1471*f*
ultraviolet light irradiation risk factor for, 1462-1463
vascular involvement of, 1465-1466
Dermatoses, neutrophilic, 184-185
Dermatosparaxis, 1810
Descending modulation, pain-selective, primary afferent fibers in, 465
Desmopressin, for hemophilia, 2012
DEXA. *see* Dual-energy x-ray absorptiometry (DEXA)
Dexamethasone sodium phosphate, usage of, 938
dGEMRIC. *see* Delayed gadolinium-enhanced MRI of cartilage (dGEMRIC)
DGLA. *see* Dihomo-γ-linolenic acid (DGLA)
DHA. *see* Docosahexaenoic acid (DHA)
DHODH. *see* Dihydroorotate dehydrogenase (DHODH)
DHPRs. *see* Dihydropyridine receptors (DHPRs)
DI. *see* Dentinogenesis imperfecta (DI)
Diabetes
"bronze," 1997
prevalence of, 1463

carpal tunnel syndrome, 2040
diffuse idiopathic skeletal hyperostosis, 2040
feet, 2040
glucocorticoids and, 953
hands, 2039-2040
muscles, 2040
in rheumatoid arthritis, 539
shoulder, 2039
type 2, and diffuse idiopathic skeletal hyperostosis, 1752-1753
Diabetic muscle infarction, 2040
Diabetic osteoarthropathy, 2040
Diabetic "stiff hand" syndrome, 2039-2040
Diagnostic arthrocentesis, availability, 785
"Dial test," 722, 722*f*
Dialysis, 1382-1384
survival rate of, 1383-1384
Diapedesis, neutrophil, 172, 174*f*
Diarthrodial joint, 1, 2*f*, 1876
developmental biology of, 1-2, 2*f*-3*f*
Diazepam, 1091-1092, 1091*f*
Dicalcium phosphate dihydrate (DCPD), deposition of, 1659
Dichotomizing lung disease, in GPA, 1546
Dickkopf-related protein 1 (DKK1), 13-14, 1753
Diet
in gout, 1110
in osteoarthritis, 1110-1111
in rheumatoid arthritis, 1109
Diet, uric acid and, 1608-1609
Dietary components, effects on inflammatory and bone destructive pathways, 1101*t*
Dietary factors, in gout, 1104
Dietary n-3 fatty acids, in rheumatoid arthritis, 1105-1107
Dietary restriction, in rheumatoid arthritis, 1109
Diffuse alveolar hemorrhage (DAH), 1356
Diffuse anterior scleritis, 650
Diffuse cutaneous systemic sclerosis, skin histology of, 1404*f*
Diffuse idiopathic skeletal hyperostosis (DISH), 663, 705-708, 1709, 1751-1757, 2040, 2041*f*
bone morphogenetic protein (BMP)-2 and, 1753
cause of, 1752-1753
characterization of, 1751, 2040
clinical manifestations of, 1753-1756, 1754*f*
complications of, 1757
diagnosis of, 1751
epidemiology of, 1751-1752
excess body weight and, 1752-1753
extraspinal involvement in, 1755-1756
familial clustering of, 1752
fracture risk in, 1756
genetic factors in, 1752
growth hormone and, 1753
heterotopic ossification and, 1756
hyperinsulinemia and, 1753
metabolic factors in, 1752-1753
nuclear factor-κB (NF-κB) and, 1753
ossified enthesopathies, 1756*f*
osteoarthritis and, 1753
pathogenesis of, 1752-1753
peripheral joint manifestations of, and osteoarthritis, 1753
prevalence of, 1751-1752
prostaglandin I2 (PGI2) and, 1753
spinal involvement in, 1754-1755
therapeutic options in, 1758*f*
thoracic spine, involvement, 705
treatment of, 706, 1756-1757
type 2 diabetes mellitus and, 1752-1753
wear-and-tear forces, 1754-1755
Wnt-β-catenin pathway and, 1753
Diffuse infiltrative lymphocytosis syndrome, 1935-1936
diagnostic criteria for, 1935
extraglandular features of, 1936*t*
parotid epithelial cyst in, aspiration of, 1936*f*
presentation of, 1935
salivary gland biopsy specimens in, 1935, 1935*f*
salivary gland enlargement in, 1935*f*
Sjögren's syndrome and, similarities and differences between, 1936*t*
snowman sign in, 1936*f*
treatment of, 1936*t*
Diffuse large B cell lymphoma, 548
Diffuse myalgias, differential diagnosis of, 774*t*
Diffuse scleroderma, edematous phase of, 1451
Diffuse skin disease, 1426-1428
Diffuse tenosynovial giant cell tumor, treatment of, 2078
Diffusing capacity of lung for carbon monoxide (DLCO), 1234
low, 1446-1447
in patient with systemic pediatric scleroderma, 1861-1862
reduction of, 1443-1444
Diflunisal, for ATTR amyloidosis, 1980
Digital flexor tenosynovitis, 809
Digital ischemia
associations of, 1434*f*
hospitalization with, 1436
treatment of, 1434-1436

  PPi-dependent mechanisms, proposal, 1648*f*
iNOS. *see* Inducible nitric oxide synthase (iNOS)
Inosine monophosphate (IMP), formation of, 1599-1600
Inside-out signaling, 415
Instability, observation of, 590
Instrument scores, measurements need, 501
Instrumentalists, arts-related musculoskeletal disorders, 527-529
Insulin, in muscles, 75
Insulin-like growth factor binding protein-1 (IGFBP-1), stimulation of, 1418
Insulin-like growth factor (IGF), 45-46
  axis, in joint homeostasis, 93
  extra-cellular PPi suppression by, 1650
Insulin-stimulated glucose uptake, resistance to, 1629
Integrin-associated protein, 175
Integrins, 43-45, 1158
  as adhesion molecules, 415
  as cell adhesion molecules, 385-386
  definition of, 289*t*
  in extra-cellular matrix, 235
  homing and, 289
  inside-out signaling, 415
  in mononuclear phagocytes, 152
  in neutrophils, 175
Intensive Diet and Exercise for Arthritis (IDEA) trial, 480
Intercellular adhesion molecules, 175
Intercritical gout, 1622, 1625
Interdigital neuroma, Morton's neuroma, injection of, 812-813
Interferon (IFN)
  IFN-α, familial aggregation and correlation, 515*f*
  inhibition, 1376
  interferon-γ, 1419
  regulatory factors, 1153-1154
  in rheumatoid arthritis, 1148
  type 1, in juvenile dermatomyositis, 1855
  type I, innate response, hijacking of, arthritogenic viruses and, 1949-1950
Interferon promoter stimulator 1 (IPS- 1), 1950
Interferon regulatory factor (IRF)
  *IRF5*, encoding, 1226
  *IRF5*, translocation of, 1333
  *IRF7*, translocation of, 1333
  *IRF8* gene, 130
Interferon-γ release assays, for tuberculosis, 1911
  and anti-TNF therapy, 1911
  concerns in, 1911
Interleukin-1 (IL-1), 1009-1012
  actions of, 1698
  anakinra, 1009-1011, 1010*f*
  in cartilage destruction, 51-52
  considerations in, 1011-1012
Interleukin-1 (IL-1) *(Continued)*
  *IL1* gene, 1962
  IL-1 Trap, 1010
  in rheumatoid arthritis
    family, 1145-1146
    receptor antagonist, 1149, 1150*f*
  superfamily cytokines, 400*t*
Interleukin-1 (IL-1) inhibitors, 1666-1668
  for juvenile idiopathic arthritis, 1834
  for systemic juvenile idiopathic arthritis, 1836-1837
Interleukin-1 receptor antagonist, 180-181
  anakinra and, 556
  in systemic juvenile idiopathic arthritis, 1821
Interleukin-1β (IL-1β), 1669
  articular chondrocyte calcification and, 1651
  in bacterial infection of joint space, 1879
  osteoarthritic cartilage specimen, immunostaining of, 1697*f*
  in systemic juvenile idiopathic arthritis, 1821
Interleukin-6 (IL-6), 1012-1016
  blockers of, 1015
  family, in rheumatoid arthritis, 1146-1147
  humanized monoclonal antibody to, 556
  mechanism of action of, 1012*f*
  sarilumab, 1015
  sirukumab, 1015
  superfamily cytokines, 402*t*
  in systemic juvenile idiopathic arthritis, 1821
  tocilizumab, 1013-1016
Interleukin-6 (IL-6) inhibitors
  for juvenile idiopathic arthritis, 1834
  for systemic juvenile idiopathic arthritis, 1836-1837
Interleukin-9 (IL-9), *IL9* gene, and juvenile idiopathic arthritis, 1819
Interleukin-10 (IL-10)
  IL-10 superfamily cytokines, 402*t*
  in rheumatoid arthritis, 1149
Interleukin-12 (IL-12) family, in rheumatoid arthritis, 1147
Interleukin-15 (IL-15), in rheumatoid arthritis, 1147
Interleukin-16 (IL-16), in bacterial infection of joint space, 1879
Interleukin-17 (IL-17)
  blockers, as emerging therapies, 1016
  targeting, 1253
Interleukin-18 (IL-18)
  in rheumatoid arthritis, 1145-1146
  in systemic juvenile idiopathic arthritis, 1821
Interleukin-23 (IL-23)
  pathway genes, and ankylosing spondylitis, 1261
  receptor gene *(IL23R)*, 1249
  signalling pathway, 1262
  and spondyloarthritis phenotype, 1249-1251, 1250*f*
  targeting, 1253
Interleukin-32 (IL-32), in rheumatoid arthritis, 1147
Interleukin-33 (IL-33), in rheumatoid arthritis, 1146
Interleukins, 1418
Intermediate peripheral joint, rheumatoid arthritis in, 1177-1178, 1177*f*
Intermittent hydrarthrosis, 786
Internal derangement, 761-763
  acute macrotrauma and, 761-762
  clinical findings of, 761, 761*f*
  degenerative joint disease, impact, 762
  etiology of, 761-762
  imaging findings of, 762
Internal derangement *(Continued)*
  management of, 762*f*
  stages, identification, 761

## Z

Zeek classification, 1515-1516
Zinc finger transcription factor (ZNF9), 1481
Zoledronic acid
for osteoporosis, 1739-1740
for Paget's disease, 1747
Zymogens, 254-255
of matrix metalloproteinases, 117-119

# Chapter Acknowledgments

**Chapter 10:** We thank Christine Holt and Amelia Molloy-Bland for the initial preparation of the manuscript, as well as present and past members of our laboratory for help with illustrations. Work in the Gordon Laboratory has been supported by the Medical Research Council, United Kingdom; the Wellcome Trust; the Arthritis Research Campaign; and the British Heart Foundation.

**Chapter 19:** This is manuscript number 21411-IMM from The Scripps Research Institute. We thank Kat Occhipinti for editorial assistance. This work was supported by National Institute of Health grants from the National Institute of Arthritis and Musculoskeletal and Skin Diseases, the National Institute of Allergy and Infectious Diseases, and the National Institute of Environmental Health Sciences.

**Chapter 33:** Dr. Tugwell holds a Canada Research Chair in Health Equity. The authors would like to thank Dr. Claire Bombardier, Ms. Ellie Pinsker, Ms. Patricia Nedanovaki, Dr. John Kirwan, and Dr. Sarah Hewlett and the OMERACT executives for their help with this manuscript.

**Chapter 43:** The authors acknowledge Dr. Nicole Rogers for her assistance with the figures. The work was supported by the Department of Veterans Affairs Veterans Health Administration, Office of Research Development, Biomedical Laboratory Research and Development to Victoria P. Werth.

**Chapter 58:** The authors thank Drs. Mette Axelsen, Anne Duer Jensen, Susanne Juhl Pedersen, Rene Poggenborg (Copenhagen); Dr. Ali Guermazi (Boston); Dr. José Raya (New York); Dr. Ida Haugen (Oslo); Dr. Fiona McQueen (Auckland) and radiographer Jakob Møller (Copenhagen) for providing images. We also thank Trine Jensen David and Henrik S. Thomsen (Copenhagen) and Pernille Bøyesen (Oslo) for critical review of parts of the text.

**Chapter 90:** Jana Vaskova provided administrative support, and departmental support was provided by the National Institute for Health Research Musculoskeletal Biomedical Research Unit, Oxford. I thank Professor Cord Sunderkoetter for his informative discussion and invaluable advice on the nature of cutaneous vasculitis.

**Chapter 116:** This chapter was supported by grants from the National Institutes of Health (HL 68705); the Gerry, Gruss, and Wildflower Foundations; the Young Family Amyloid Research Fund; and the Amyloid Research Fund at Boston University.
